DISSERTATION

Presented to the Faculty of the Graduate School of
The University of Texas at Austin
in Partial Fulfillment
of the Requirements
for the Degree of

DOCTOR OF PHILOSOPHY

THE UNIVERSITY OF TEXAS AT AUSTIN

December 2012

Dedicated to my parents.

Acknowledgments

At the beginning, I would like to acknowledge the support of the National Science Foundation during the course of my research. My first thanks must go to my advisor, John Hasenbein. He gave me lots of support in my research. His advice was always very helpful to me. Thus I have to attribute most of my success to his guidance through most of my years here. He made my path to finish this degree easy. Next I would like to thank all the other professors in the Graduate Program in Operations Research and Industrial Engineering. They also gave me lots of suggestions on my course works and research during my study. Of course, I also need to thank our fellow graduate students. They made the social, academic and all other aspects of my years at UT the most enjoyable of my life. Finally, I need to thank Meimeizi Zhu for all of her love and support during this time.

Variational Problems for Semi-Martingale Reflected Brownian Motion in the Octant

Publication No. _____

The University of Texas at Austin, 2012

Supervisor: John Hasenbein

Understand the behavior of queueing networks in heavy traffic is very important due to its importance in evaluating the network performance in related applications. However, in many cases, the stationary distributions of such networks are intractable. Based on diffusion limits of queueing networks, we can use Reflected Brownian Motion (RBM) processes as reasonable approximations. As such, we are interested in obtaining the stationary distribution of RBM. Unfortunately, these distributions are also in most cases intractable. However, the tail behavior (large deviations) of RBM may give insight into the stationary distribution. Assuming that a large deviations principle holds, we need only solve the corresponding variational problem to obtain the rate function. Our research is mainly focused on how to solve variational problems in the case of rotationally symmetric (RS) data.

The contribution of this dissertation primarily consists of three parts. In the first part we give out the specific stability condition for the RBM in the octant in the RS

case. Although the general stability conditions for RBM in the octant has been derived previously, we simplify these conditions for the case we consider. In the second part we prove that there are only two types of possible solutions for the variational problem. In the last part, we provide a simple computational method. Also we give an example under which a spiral path is the optimal solution.

Introduction

The study of queueing networks is very important for understanding complex stochastic systems. In manufacturing, telecommunication, and service system models, the corresponding stationary distribution can give useful insight into system operation. One of the most basic queueing networks is the Jackson network, which was first described in [24] and [25]. For this kind of network the stationary distribution, which is of product form, can be derived. However, in most other more complicated cases, the stationary distribution is intractable. The study of the queue is even more important when it is in heavy traffic. Thus the ability to model the heavy traffic queueing system accurately is crucial. Since the stationary distribution is unavailable, often the only fruitful methods of analysis are simulation or numerical methods. However, such methods may require prohibitive computation time and they often do not provide much insight. Another alternative is to use approximations, especially those that are more accurate when the system is close to saturation. Weak convergence theory implies that a diffusion process could be a good approximation for the waiting-time process. The study of diffusion and fluid limits turns to be very important in this sense. [27] is a very good introduction to this motivation and [10] elaborates on this background.

Reiman [32] first established a diffusion approximation for generalized open Jackson network under heavy traffic. The foundation of his work was [19]. Later Chen and Mandelbaum established diffusion approximations without assuming the heavy traffic condition for both open and closed networks in [8]. On the other hand, Johnson [26] and Chen and Mandelbaum [7] established fluid approximation for the generalized Jackson network. Besides the generalized Jackson network, the more complicated multiclass queueing network also garnered much interest, starting in the 1990's. Peterson [31] first studied a multiclass feedforward queueing network to derive a heavy traffic limit theorem. The reflected Brownian motion (RBM) arising from a heavy traffic limit theorem was studied by Harrison and Williams [22]. For more general Brownian approximations, important results were established in [9] and [18]. Due to this pioneering work, interest grew in analyzing the stationary distribution of RBM. Harrison and Williams [20] and Chen [6] made significant contributions on RBM in the orthant. Also, Harrison et al. [23] characterized the stationary distribution of RBM on a unit simplex. Unfortunately, in general the stationary distribution of RBM is also intractable. However, the study of large deviations can give some insight into computing the stationary distribution.

In this dissertation, we analyze the large deviations principle (LDP) for semi-martingale reflected Brownian motion (SRBM) in the orthant, and its application in multiclass queueing networks. It is known that the SRBM processes of interest arises from heavy traffic limits of queueing network processes. Understanding the tail asymptotics of the SRBM's can aid in computing their stationary distribution, which in turn gives insight into the behavior of the pre-limit queueing processes. The

LDP gives rise to a variational problem, the solution to which may indicate how large queues build up in multiclass queueing networks. There arises then the interesting question of solving the variational problem associated with the SRBM. Due to the difficulty of the general problem, in this dissertation we consider some special cases of SRBM, which we called *rotationally symmetric* (RS-SRBM). In this case, we are able to obtain the conditions under which the optimal solutions to the variational problem are gradual paths (each piece is strictly increasing in dimension) or spiral paths around the boundary of the octant.

Next, we briefly review the structure in the analysis of large deviations and the previous related work. The typical analysis of large deviations for any process can often be divided into two steps: (1) proving an LDP review some previous results. First, with respect to step (1), an LDP for SRBM's in \mathbb{R}_+^d has only been established for special cases. For a general dimension d , Majewski examined the special cases of SRBM's arising from feed-forward queueing networks [28] and SRBM's whose reflection matrix is an M -matrix (as defined in Bermon and Plemmons [3]) [29]. Dupuis and Ramanan [15] obtained an LDP for a generalization of the Harrison-Reiman case. It should be noted that these results still leave the LDP for $d = 2$ unresolved for some parameter cases (see [17] for a summary). More recently, Dai and Miyazawa [12] obtained exact asymptotics for SRBM in two dimensions using moment generating functions and techniques from complex analysis. However, the results are limited to asymptotic behavior along a ray of the quadrant. In a related follow-up paper, Dai and Miyazawa [13] provide new insights into the results of Avram et al. [2] and derive exact asymptotics for the boundary measures of SRBM in two dimensions.

The tasks outlined for step (2) are best explained by examining the case in two dimensions. In this setting, Avram et al. [2] and Harrison and Hasenbein [17] gave a complete analytical solution to the variational problem for any SRBM of interest (e.g., those possessing a stationary distribution). The analysis was carried out in a few steps. First, three general properties of optimal paths were established: convexity, scaling, and merging. Second, these properties were used to conclude that only three types of optimal paths are possible. Finally, these path properties allow the development of a complete algebraic description of the optimal paths in two dimensions. Unfortunately, the situation in three dimensions is considerably more difficult [1]. While the properties of convexity, scaling, and merging still apply, they are nowhere near sufficient to characterize the possible optimal paths. In order to attack the higher dimensional problem, we examine the RS-SRBM cases and develop new techniques for restricting the types of paths which must be examined.

The main contribution of the research is to clarify the nature of optimal paths in three-dimensional variational problems and to provide new techniques to achieve this analysis. To best elucidate our contribution, we present our main result now:

Theorem 1. *Consider a rotationally symmetric variational problem, as given in Definition 7, arising from SRBM in \mathbb{R}_+^3 . Suppose $\Gamma = I$ and $\theta < 0$. Under Conditions 1 and 2 in Chapter 4, there always exists an optimal path which is either (a) a gradual path (a path which moves through faces of strictly increasing dimension) or (b) a classic spiral path.*

Theorem 20 establishes part (a) and Theorem 22 establishes part (b). An important consequence of this result is the following:

Corollary 2. *For the variational problem arising from SRBM in the octant, there exists an example of an optimal spiral path.*

This follows from Theorem 1 and the calculations in Chapter 4.

To the best of our knowledge, this is the first time a spiral path has been shown to be optimal for this type of variational problem. Conditions 1 and 2 are somewhat complicated and we discuss them in detail later. The most important restriction they impose is that the SRBM must have reflection vectors which point “outward.” We believe that this condition, along with the covariance matrix condition, can be relaxed. Note that the negativity condition on the drift θ is not restrictive, since it is equivalent in our case to requiring stability of the associated SRBM.

An implication of these results is that they provide the basis for tractable numerical methods for computing optimal paths in three dimensions. Complementary to our work is a recent paper by El Kharroubi et al. [16], which provides some algebraic results for paths in three dimensions. However, most of the results in [16] require *a priori* elimination of certain optimal path types, which we are able to provide. Important related computational methodology appeared in Majewski [29]. If one fixes the maximum number of segments in the search for an optimal path, Majewski’s branch-and-bound algorithm can efficiently produce the desired path.

This dissertation contains five parts. The first part provides the previous results and gives an outline of our main results. The second part gives an example relating a queueing network with the SRBM approximation. Then we introduce the definition of the SRBM and its associated variational problem. There the motivation

for studying the variational problem becomes apparent. Also we can see how to use SRBM to approximate queueing networks. More specifically, we show how to match the parameters between the generalized Jackson network and the RS-SRBM. This mainly follows [10] but most results can be simplified in our special cases. The third part discusses the stability conditions for the RS-SRBM. The study of stability is a necessary prerequisite for solving the variational problem. Only with the existence of a stationary distribution, is it meaningful to solve the variational problem. In this part we use the results from [5]. As a result, this study gives us more restrictions on the parameters we use in the RS-SRBM. The fourth part contains the detailed derivation of our main results on optimal paths in the variational problem associated with the LDP. The fifth part provides computational results and analysis. We give an example of the variational problem for which the optimal path can be characterized based on our main result. Also we delineate a general scheme for solving the variational problem numerically in some special cases. We would like to answer the following question: Given the parameters, can we identify the path that is optimal for the corresponding variational problem and compute the corresponding cost? The last part discusses some potential future work. As the problem we solved in our research is a special case, it is important to check whether the results still hold in more general cases.

Chapter 2

The Variational Problem, SRBM, Large Deviations and Generalized Jackson Network

In this chapter we briefly introduce the concept of variational problem, SRBM, large deviations principle and the generalized Jackson network. We also define the rotational symmetric case that we use in later chapters. Finally, we provide the relation between the generalized Jackson network and the approximating SRBM.

2.1 The Variational Problem

In this section, we define the variational problem of interest in our research. First, we give notation and definitions which follow as closely as possible to those given in Avram et al. [2].

Let $d \geq 1$ be an integer and θ a constant vector in \mathbb{R}^d . Also, Γ is a $d \times d$ symmetric and strictly positive definite matrix, and R is a $d \times d$ matrix. The triple (θ, Γ, R) provides the data to variational problems and, as described later, associated reflected Brownian motion processes. Throughout this dissertation, all vector inequalities should be interpreted componentwise and all vectors are assumed

to be column vectors. Finally, for vectors $v \in \mathbb{R}^d$ and $w \in \mathbb{R}^d$ we define the inner product

$$\langle v, w \rangle = v' \Gamma^{-1} w$$

and the associated norm $\|v\| = \sqrt{\langle v, v \rangle}$.

In order to more easily define the VP, we first introduce the Skorohod problem associated with the matrix R . Thus, let $C([0, \infty), \mathbb{R}^d)$ be the set of continuous functions $x : t \in [0, \infty) \rightarrow x(t) \in \mathbb{R}^d$. A function $x \in C([0, \infty), \mathbb{R}^d)$ is called a path and is often denoted by $x(\cdot)$. We now define the Skorohod problem associated with a reflection matrix R .

Definition 1 (The Skorohod Problem). Let x be a path. An R -regulation of x is a pair of paths $(z, y) \in C([0, \infty), \mathbb{R}^d) \times C([0, \infty), \mathbb{R}^d)$ such that

$$z(t) = x(t) + R y(t), \quad t \geq 0, \tag{2.1}$$

$$z(t) \geq 0, \quad t \geq 0, \tag{2.2}$$

$$y(\cdot) \text{ is non-decreasing, } y(0) = 0, \tag{2.3}$$

$$\int_0^\infty z_i(s) dy_i(s) = 0, \quad i = 1, \dots, d. \tag{2.4}$$

When the R -regulation (y, z) of x is unique for each $x \in C([0, \infty), \mathbb{R}^d)$, the mapping

$$\psi : x \rightarrow \psi(x) = z$$

is called the reflection mapping from $C([0, \infty), \mathbb{R}^d)$ to $C([0, \infty), \mathbb{R}_+^d)$. When the triple (x, y, z) is used, it is implicitly assumed that (y, z) is an R -regulation of x .

An important issue when defining the Skorohod problem is whether a solution exists for any given path x . If the reflection matrix R is completely- \mathcal{S} , as defined below, then indeed there is a solution for every x with $x(0) \geq 0$ (see Mandelbaum [30] and Bernard and El Kharroubi [4]).

Definition 2. A $d \times d$ matrix R is said to be an \mathcal{S} -matrix if there exists a $u > 0$ such that $Ru > 0$. The matrix R is *completely- \mathcal{S}* if each principal submatrix of R is an \mathcal{S} -matrix.

The class of \mathcal{P} -matrices, defined below, also plays an important role in the development of SRBM theory and associated variational problems.

Definition 3. A $d \times d$ matrix R is said to be a \mathcal{P} -matrix if all of its principal minors are positive.

In addition to the issue of existence of solutions to the Skorohod problem, there is also the matter of the uniqueness of the solution, for a given path x . It is useful when defining the VP to have a notational convention which applies when solutions are not unique. To this end, we assume that if the Skorohod problem is non-unique, then $\psi(x)$ represents a set of paths (solutions) corresponding to x . Furthermore, the expression

$$\psi(x)(T) = v$$

indicates that there exists a $z \in \psi(x)$ such that $z(T) = v$.

We now define the variational problem studied in the dissertation.

Definition 4 (The Variational Problem).

$$I(v) \equiv \inf_{T \geq 0} \inf_{x \in \mathcal{H}^d, \psi(x(\cdot))(T)=v} \frac{1}{2} \int_0^T \|\dot{x}(t) - \theta\|^2 dt \quad (2.5)$$

where \mathcal{H}^d is the space of all absolutely continuous functions $x(\cdot) : [0, \infty) \rightarrow \mathbb{R}^d$ which have square integrable derivatives on bounded intervals and have $x(0) = 0$.

Definition 5. Let $v \in \mathbb{R}_+^d$. If a given triple of paths (x, y, z) is such that the triple satisfies the Skorohod problem, $z(T) = v$ for some $T \geq 0$, and

$$\frac{1}{2} \int_0^T \|\dot{x}(t) - \theta\|^2 dt = I(v),$$

then we will call (x, y, z) an *optimal triple*, for VP (2.5), with optimal value $I(v)$. The function z is called an *optimal path* if it is the last member of an optimal triple. Such a triple (x, y, z) is also sometimes referred to as a *solution* to the VP (2.5). T is called the *optimal time* for such a solution.

2.2 Semi-martingale Reflected Brownian Motion

We now define the SRBM on the positive orthant associated with the data (θ, Γ, R) . Let \mathcal{B} denotes the σ -algebra of Borel subsets of \mathbb{R}_+^d . A triple $(\Omega, \mathcal{F}, \{\mathcal{F}_t\})$ is called a *filtered space* if Ω is a set, \mathcal{F} is a σ -field of subsets of Ω , and $\{\mathcal{F}_t\} \equiv \{\mathcal{F}_t, t \geq 0\}$ is an increasing family of sub- σ -fields of \mathcal{F} , i.e., a filtration. If, in addition, \mathbb{P} is a probability measure on (Ω, \mathcal{F}) , then $(\Omega, \mathcal{F}, \{\mathcal{F}_t\}, \mathbb{P})$ is called a filtered probability space.

Definition 6 (SRBM). Given a probability measure ν on $(\mathbb{R}_+^d, \mathcal{B})$, a *semi-martingale reflecting Brownian motion* associated with the data (θ, Γ, R, ν) is an $\{\mathcal{F}_t\}$ -adapted,

d -dimensional process Z defined on some filtered probability space $(\Omega, \mathcal{F}, \{\mathcal{F}_t\}, \mathbb{P}_\nu)$ such that

- (i) \mathbb{P}_ν -a.s., Z has continuous paths and $Z(t) \in \mathbb{R}_+^d$ for all $t \geq 0$,
- (ii) $Z = X + RY$, \mathbb{P}_ν -a.s.,
- (iii) under \mathbb{P}_ν ,
 - (a) X is a d -dimensional Brownian motion with drift vector θ , covariance matrix Γ and $X(0)$ has distribution ν ,
 - (b) $\{X(t) - X(0) - \theta t, \mathcal{F}_t, t \geq 0\}$ is a martingale,
- (iv) Y is an $\{\mathcal{F}_t\}$ -adapted, d -dimensional process such that \mathbb{P}_ν -a.s. for each $j = 1, \dots, d$,
 - (a) $Y_j(0) = 0$,
 - (b) Y_j is continuous and non-decreasing,
 - (c) Y_j can increase only when Z is on the face $F_j \equiv \{x \in \mathbb{R}_+^d : x_j = 0\}$,
i.e., $\int_0^\infty Z_j(s) dY_j(s) = 0$.

An SRBM associated with the data $(\mathbb{R}_+^d, \theta, \Gamma, R)$ is an $\{\mathcal{F}_t\}$ -adapted, d -dimensional process Z together with a family of probability measures $\{\mathbb{P}_x, x \in \mathbb{R}_+^d\}$ defined on some filtered space $(\Omega, \mathcal{F}, \{\mathcal{F}_t\})$ such that, for each $x \in \mathbb{R}_+^d$, (i)-(iv) hold with $\mathbb{P}_\nu = \mathbb{P}_x$ and ν being the point distribution at x .

Recall that the parameters θ , Γ and R are called the *drift vector*, *covariance matrix* and *reflection matrix* of the SRBM, respectively. The results of Reiman and Williams [33] and Taylor and Williams [35] imply that the necessary and sufficient conditions for the existence the SRBM is that R is completely- \mathcal{S} .

The measure ν on $(\mathbb{R}_+^d, \mathcal{B})$ is a stationary distribution for an SRBM Z if for each $A \in \mathcal{B}$,

$$\nu(A) = \int_{\mathbb{R}_+^d} \mathbb{P}_x\{Z(t) \in A\} \nu(dx) \quad \text{for each } t \geq 0. \quad (2.6)$$

When ν is a stationary distribution, the process Z is stationary under the probability measure \mathbb{P}_ν . In our discussion below, we are concerned only with the (unique) stationary distribution for the SRBM with data (θ, R, Γ) and therefore we drop the ν notation.

2.3 Large Deviations

The motivation for studying the variational problem comes from the theory of large deviations. Some good references for this topic are Dembo and Zeitouni [14] or Shwartz and Weiss [34]. For SRBM's in the d -dimensional orthant, we have the following statement of the large deviations principle, which has only been established for some special cases, as noted in the introduction.

Conjecture 3 (General Large Deviations Principle). *Consider an SRBM Z with data (θ, Γ, R) . Suppose that R is a completely- \mathcal{S} matrix and that there exists a probability measure \mathbb{P}_π under which Z is stationary. Then for every measurable $A \subset \mathbb{R}_+^d$*

$$\limsup_{u \rightarrow \infty} \frac{1}{u} \log \mathbb{P}_\pi(Z(0)/u \in A) \leq - \inf_{v \in A^c} I(v) \quad (2.7)$$

and

$$\liminf_{u \rightarrow \infty} \frac{1}{u} \log \mathbb{P}_\pi(Z(0)/u \in A) \geq - \inf_{v \in A^o} I(v) \quad (2.8)$$

where A^c and A^o are respectively the closure and interior of A .

2.4 A Generalized Jackson Network (GJN)

In this section, we give an example of three-station Jackson network and it can be seen later how it can be related to the SRBM. A Jackson network is one of the most basic and commonly studied networks in queueing theory. Further, it can be generalized by relaxing the assumption of Poisson arrival processes and exponential service times. Unlike the Jackson network, the stationary distribution of a generalized Jackson network usually does not have an explicit analytical form. So approximations are very helpful to analyze this type of network. First of all, we provide the basic notation pertaining to GJNs. Consider a network consisting of N single-server stations. Each station has an infinite buffer. Let P be the routing matrix with $P = (P_{j,k})$. $A_j(t)$ is the number of jobs that have arrived at station j exogenously during $(0, t]$. μ_j is the service rate of station j . Let \mathcal{E} be the set of stations that have exogenous arrivals. α_j is the exogenous arrival rate of station j for $j \in \mathcal{E}$ while λ_j is the effective arrival rate of station j . Let $v_j = \{v_j(l), l \geq 1\}$ be an i.i.d. sequence with $v_j(l)$ indicating the service time of l th job at station j . c_j is the coefficient of variation of $v_j(1)$. Finally, we define $c_{0,j}$ to be the coefficient of variation of the interarrival times of A_j when $j \in \mathcal{E}$ and 0 otherwise.

The **rotationally symmetric generalized Jackson network** (RS-GJN)

Figure 2.1: Rotationally Symmetric Generalized Jackson Network

will be introduced here and we show later how to compute the parameters for the corresponding the RS-SRBM. Figure 2.1 depicts such a GJN with three stations.

The rates of the exogenous arrival processes and the service processes are α_0 and μ_0 , respectively, at each station. The routing matrix is

$$P = \begin{pmatrix} 0 & p_1 & p_2 \\ p_2 & 0 & p_1 \\ p_1 & p_2 & 0 \end{pmatrix}.$$

Further assume that $c_{0,j} = c_0$ and $c_j = c$, $\forall j$. This means that both arrival and service times have equal variance at all stations. The notations in this example can be extended to the network with an arbitrary number of stations.

2.5 Symmetric SRBM

Consider the RS-GJN example given in the last subsection. Follow the same idea we now define the rotationally symmetric SRBM (RS-SRBM) and VP. Further there is a more restrictive case which is called a mirror symmetric SRBM (MS-SRBM). These symmetries, while restrictive, provide a considerable simplification of the analysis.

Definition 7. For $d = 3$ the data (θ, Γ, R) is said to be **rotationally symmetric** if all of the following three conditions hold:

1. R has the form

$$R = \begin{pmatrix} 1 & r_2 & r_1 \\ r_1 & 1 & r_2 \\ r_2 & r_1 & 1 \end{pmatrix}.$$

2. The drift has the form $\theta = (\theta_0, \theta_0, \theta_0)'$.

3. The covariance matrix has the form

$$\Gamma = \begin{pmatrix} \sigma^2 & \rho\sigma^2 & \rho\sigma^2 \\ \rho\sigma^2 & \sigma^2 & \rho\sigma^2 \\ \rho\sigma^2 & \rho\sigma^2 & \sigma^2 \end{pmatrix},$$

where $-1 < \rho < 1$.

Some statements in the rest of this dissertation relate only to R and in this case we call R alone rotationally symmetric if and only if R has the form given in the definition above. We employ a similar convention for Γ .

Definition 8. For $d = 3$ the data (θ, Γ, R) is said to be **mirror symmetric** if it is rotationally symmetric and in addition $r_1 = r_2$.

Notice that the rotationally symmetric Γ matrix also appears to be mirror symmetric. Since covariance matrices are by definition symmetric (in the standard matrix algebra sense), there is no sensible way to define a rotationally symmetric Γ which is not also mirror symmetric. For a rotationally symmetric Γ we have the following result, which will be used in demonstrating optimal path properties.

Lemma 4. *If Γ is rotationally symmetric, then*

$$\Gamma^{-1} = \sigma^{-2} \begin{pmatrix} \gamma_0 & \gamma_1 & \gamma_1 \\ \gamma_1 & \gamma_0 & \gamma_1 \\ \gamma_1 & \gamma_1 & \gamma_0 \end{pmatrix},$$

with $\gamma_0 > \gamma_1$.

Proof of Lemma 4. It can be checked that if Γ^{-1} has the form of the lemma, then for a rotationally symmetric matrix Γ the nine equations in $\Gamma\Gamma^{-1} = I$ are consistent. Since matrix inverses are unique, it follows immediately that Γ^{-1} can be written as stated in the lemma. Next, in order for $\Gamma\Gamma^{-1} = I$ to hold we must have

$$\begin{aligned} \gamma_0 + 2\rho\gamma_1 &= 1 & \text{and} \\ \gamma_1 + \rho(\gamma_0 + \gamma_1) &= 0. \end{aligned}$$

Solving these equations yields

$$\rho = -\frac{\gamma_1}{\gamma_0 + \gamma_1} = \frac{1 - \gamma_0}{2\gamma_1}, \tag{2.9}$$

which implies

$$2\gamma_1^2 = (\gamma_0 - 1)(\gamma_0 + \gamma_1). \quad (2.10)$$

Note that $\gamma_0 = 0$ is not possible. To prove $\gamma_0 > \gamma_1$ we examine four cases.

1. If $\gamma_0 > 0$ and $\gamma_1 \leq 0$ then the result follows immediately.
2. Suppose $\gamma_0 > 0, \gamma_1 > 0$ and $\gamma_0 \leq \gamma_1$. Then we have

$$(\gamma_0 - 1)(\gamma_0 + \gamma_1) \leq (\gamma_1 - 1)(\gamma_1 + \gamma_1) < 2\gamma_1^2.$$

This contradicts (2.10).

3. Suppose $\gamma_0 < 0, \gamma_1 \leq 0$ and $\gamma_0 \leq \gamma_1$. Then we have

$$(\gamma_0 - 1)(\gamma_0 + \gamma_1) \geq (\gamma_1 - 1)(\gamma_1 + \gamma_1) > 2\gamma_1^2.$$

This again contradicts (2.10).

4. Suppose finally that $\gamma_0 < 0, \gamma_1 > 0$ and $\gamma_0 \leq \gamma_1$. Since $\rho < 1$ by definition, (2.9) implies that $-2\gamma_1 + 1 < \gamma_0 < 0$. Solving (2.10) gives

$$\gamma_0 = \frac{1 - \gamma_1 - \sqrt{9\gamma_1^2 + 2\gamma_1 + 1}}{2} < \frac{1 - \gamma_1 - 3\gamma_1}{2} = -2\gamma_1 + 1/2,$$

which contradicts $-2\gamma_1 + 1 < \gamma_0$. In solving (2.10) we take the smaller root, since we must have $\gamma_0 < 0$.

Thus, by contradiction, we have established $\gamma_0 > \gamma_1$. □

Some readers may also be familiar with the skew-symmetry condition (see [20, 21]) which is

$$2\Gamma = RD^{-1}\Lambda + \Lambda D^{-1}R', \quad (2.11)$$

where $D = \text{diag}(R)$ and $\Lambda = \text{diag}(\Gamma)$. This condition is necessary and sufficient for the stationary density function of the SRBM to admit a separable, exponential form. Our notions of symmetry do not coincide in any meaningful way with the notion of skew-symmetry. It can be checked that rotationally symmetric SRBM data is also skew-symmetric if and only if $r_1 + r_2 = 2\rho$.

2.6 Parameter Matching between GJN and SRBM

In this subsection we provide the mappings between GJN and SRBM parameters as outlined in [10] in the 3-D case. Recall all the notation in Section 2.4 . Also, vector μ is the service rate, α the exogenous arrival rate, and λ the effective arrival rate. Given the N dimensional SRBM associated with (θ, Γ, R) , it is known (cf. [10]) that the following hold:

1. $R = I - P'$,
2. $\theta = \alpha - (I - P')\mu$,
3. $\Gamma = \Gamma_{(k,l)}$ where

$$\Gamma_{(k,l)} = \sum_{j=1}^N (\lambda_j \wedge \mu_j) [p_{j,k}(\delta_{k,l} - p_{j,l}) + c_j^2(p_{j,k} - \delta_{j,k})(p_{j,k} - \delta_{j,k})] + \alpha_k c_{0,k}^2 \delta_{k,l},$$

here $\delta_{k,l}$ is an indicator function whose value is 1 if $k = l$ and 0 otherwise.

Our task is to show that there is a one-to-one mapping on first and second moment between the RS-GJN and RS-SRBM defined above. It needs to mention that this one to one mapping doesn't imply that for each RS-SRBM there is a unique RS-GJN that can map to it since we have no idea on the distribution of arrival and service for the queueing network. It is only the mapping of parameters and provides the way to approximate the queueing network by SRBM.

First for a given RS-GJN, we indicate how to obtain the parameters for the corresponding RS-SRBM. In the 3-D RS-GJN, it is clear that

$$P = \begin{pmatrix} 0 & p_1 & p_2 \\ p_2 & 0 & p_1 \\ p_1 & p_2 & 0 \end{pmatrix}$$

and

$$R = I - P' = \begin{pmatrix} 1 & -p_2 & -p_1 \\ -p_1 & 1 & -p_2 \\ -p_2 & -p_1 & 1 \end{pmatrix}.$$

So $r_1 = -p_1$, $r_2 = -p_2$. For θ we have:

$$\theta = \alpha - (I - P')\mu = (\alpha_0 - (1 - p_1 - p_2)\mu_0, \alpha_0 - (1 - p_1 - p_2)\mu_0, \alpha_0 - (1 - p_1 - p_2)\mu_0)'$$

Let $\lambda = (I - P')^{-1}\alpha = (\lambda_0, \lambda_0, \lambda_0)'$. Thus $\theta_0 = \alpha_0 - (1 - p_1 - p_2)\mu_0 = (1 - p_1 - p_2)(\lambda_0 - \mu_0)$.

The sufficient and necessary condition for an SRBM to be stable requires that $R^{-1}\theta < 0$, which is equivalent to $\theta < 0$ [5]. This implies that $\lambda_0 < \mu_0$ and

$1 - p_1 - p_2 > 0$, which are indeed the stability conditions for the GJN. The routing matrix P has the property that $P_{1,2} = P_{2,3} = P_{3,1} = p_1$, $P_{2,1} = P_{3,2} = P_{1,3} = p_2$. For $k \neq l$,

$$\Gamma_{k,l} = \lambda_0(-p_1 p_2 + c^2(p_1 p_2 - p_1 - p_2)).$$

Note that $\Gamma_{k,l}$ is actually independent of k and l . For $k = l$,

$$\Gamma_{k,l} = \lambda_0[p_1(1 - p_1) + p_2(1 - p_2) + c^2(1 + p_1^2 + p_2^2)] + \alpha_0 c_0^2.$$

Again, this is independent of k and l . Therefore, the covariance matrix indeed follows the form of Γ in RS-SRBM.

Now we would like to see whether given the triple (θ, Γ, R) of RS-SRBM, the corresponding parameters (first and second moment, routing matrix, etc.) of RS-GJN are also unique. One extra condition required is that c_j^2 is proportional to $\frac{1}{\mu_j^2}$. So there exists a c' s.t. $c_j^2 = c'^2 / \mu_j^2, \forall j$.

Further, assume that $r_1 \neq r_2$ so the R matrix is rotationally symmetric, it is clear that

$$P = I - R' = \begin{pmatrix} 0 & -r_1 & -r_2 \\ -r_2 & 0 & -r_1 \\ -r_1 & -r_2 & 0 \end{pmatrix}.$$

It can be seen that if $r_1, r_2 < 0$ then P is a rotationally symmetric routing matrix with $P_{1,2} = P_{2,3} = P_{3,1} = -r_1$, $P_{2,1} = P_{3,2} = P_{1,3} = -r_2$. Also it is clear that

$$\Gamma_{1,2} = \lambda_3 r_1 r_2 (c_3^2 - 1) + \lambda_1 c_1^2 r_1 + \lambda_2 c_2^2 r_2,$$

and

$$\Gamma_{2,1} = \lambda_3 r_1 r_2 (c_3^2 - 1) + \lambda_1 c_1^2 r_2 + \lambda_2 c_2^2 r_1.$$

Applying $\Gamma_{1,2} = \Gamma_{2,1}$ and $c_j^2 = \frac{c'^2}{\mu_j^2}, \forall j$, we have that

$$\frac{\lambda_1}{\mu_1^2} = \frac{\lambda_2}{\mu_2^2}.$$

It can be concluded that

$$\frac{\lambda_1}{\mu_1^2} = \frac{\lambda_2}{\mu_2^2} = \frac{\lambda_3}{\mu_3^2} = K \text{ for a constant } K > 0.$$

On the other hand,

$$\Gamma_{1,3} = \lambda_2 r_1 r_2 (c_2^2 - 1) + \lambda_1 c_1^2 r_2 + \lambda_2 c_2^2 r_1.$$

Applying $\Gamma_{1,2} = \Gamma_{1,3}$ and noticing that $\lambda_j c_j^2 = c'^2$, we have $\lambda_3 r_1 r_2 = \lambda_2 r_1 r_2$. So λ_j is a constant for all j . The equality $\theta = \alpha - (I - P')\mu = (I - P')(\lambda - \mu)$ implies that $\lambda - \mu = (I - P')^{-1}\theta = R^{-1}\theta$.

It is known from Lemma 5 that if R is rotationally symmetric then its inverse R^{-1} must be of form

$$\begin{pmatrix} a & b & c \\ c & a & b \\ b & c & a \end{pmatrix},$$

and $(a + b + c)(1 + r_1 + r_2) = 1$.

This implies that $\lambda_j - \mu_j = \frac{\theta_0}{1+r_1+r_2}, \forall j$. Thus μ_j is also a constant for all j . Then it is clear that $\alpha_j, c_{0,j}$ and c_j are all independent of j . This shows that if a GJN can be approximated by an RS-SRBM then it is an RS-GJN given some restrictions on the variance of the service rates.

Chapter 3

SRBM Stability Conditions

For SRBM in three dimensions Bramson et al. [5] obtained results which, in addition to previous results, give a complete characterization of existence and stability of SRBM. This characterization is summarized in Figure 3.1. The results of this section specialize their results for RS-SRBM. First, however, we need to define a few terms appearing in the figure.

We define the solutions to the *linear complementarity problem* (LCP) in dimension d as follows (see [11] for background). Vectors $u, v \in \mathbb{R}^d$ comprise a solution to the LCP if

$$\begin{aligned}u, v &\geq 0 \\ v &= \theta + Ru \\ u \cdot v &= 0.\end{aligned}$$

Using the terminology in [5] a solution (u, v) to the LCP is called *stable* if $v = 0$ and the solution is called *divergent* otherwise. The existence or non-existence of a solution to the LCP must be checked in the bottom decision point in Figure 3.1.

Bramson et al. [5] also define various subsets of the data pairs (θ, R) which

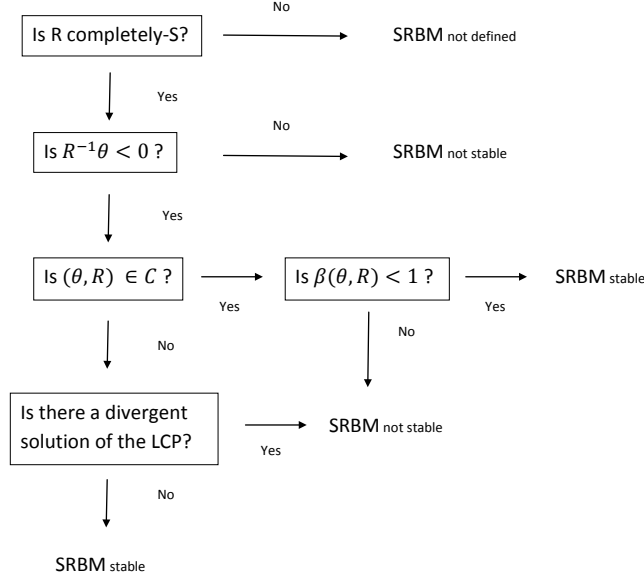

Figure 3.1: Existence and Stability of SRBM in the Octant

relate to the third line of decision points in Figure 3.1. To avoid overlapping notation we specialize their definitions now to the RS-SRBM case.

First, for a pair (θ, R) ,

$$C_1 = \{(\theta_0, r_1, r_2) : \theta_0 < 0, r_1 < 1, r_2 > 1\} \quad \text{and}$$

$$C_2 = \{(\theta_0, r_1, r_2) : \theta_0 < 0, r_1 > 1, r_2 < 1\},$$

with $C = C_1 \cup C_2$.

Next, for a data pair $(\theta, R) \in C_1$,

$$\beta(\theta, R) = \left(\frac{1 - r_2}{r_1 - 1} \right)^3$$

and for $(\theta, R) \in C_2$

$$\beta(\theta, R) = \left(\frac{r_1 - 1}{1 - r_2} \right)^3.$$

For general SRBM data $\beta(\theta, R)$ depends on θ but in the rotationally symmetric case the dependence disappears. These definitions are related to spiral piecewise linear solutions of the Skorohod problem. Section 3 in [5] should be consulted for an in-depth explanation of how these expressions arise.

We are now prepared to present a series of lemmas which lead to the main stability result of this section. The first lemma probably appears in a textbook somewhere, but we state it here and prove it for completeness. For later use, note that the lemma implies that $a + b + c \neq 0$. All the results stated in this section apply to the three-dimensional case.

Lemma 5. *If a reflection matrix R is non-singular and rotationally symmetric then its inverse must be of the form*

$$R^{-1} = \begin{pmatrix} a & b & c \\ c & a & b \\ b & c & a \end{pmatrix},$$

and $(a + b + c)(1 + r_1 + r_2) = 1$.

Proof. It can be checked that if R^{-1} has the form of the lemma, then for a rotationally symmetric matrix R the nine equations in $RR^{-1} = I$ are consistent. Since matrix inverses are unique, it follows immediately that R^{-1} can be written as stated in the

lemma. Also, from $RR^{-1} = I$, we have

$$\begin{aligned} a + r_2c + r_1b &= 1 \\ b + r_2a + r_1c &= 0 \\ c + r_2b + r_1a &= 0. \end{aligned}$$

Summing these equations gives the claimed equality. \square

Since existence of an SRBM requires that R is completely- \mathcal{S} , our first task is derive a simple condition to insure that this characterization holds.

Lemma 6. *Suppose a matrix R is rotationally symmetric. Then R being completely- \mathcal{S} is equivalent to $1 + r_1 + r_2 > 0$.*

Proof. First suppose R is completely- \mathcal{S} and $1 + r_1 + r_2 \leq 0$. We derive a contradiction. Since R is completely- \mathcal{S} , there exists a vector $u \equiv (u_1, u_2, u_3)' > 0$ such that $Ru > 0$. Summing the equations in $Ru > 0$ we have

$$(1 + r_1 + r_2)(u_1 + u_2 + u_3) > 0. \quad (3.1)$$

But if $1 + r_1 + r_2 \leq 0$, then there is no $u > 0$ satisfying (3.1), which is a contradiction. So, we have proven that completely- \mathcal{S} implies $1 + r_1 + r_2 > 0$ which is one direction of the equivalence.

Now assume that $1 + r_1 + r_2 > 0$. Then note that $u = (1, 1, 1)'$ satisfies $Ru > 0$. This implies that R is an \mathcal{S} -matrix. We must now verify that the two-by-two principal submatrices are also \mathcal{S} -matrices. These submatrices take the form

$$S_1 = \begin{pmatrix} 1 & r_2 \\ r_1 & 1 \end{pmatrix} \quad \text{and} \quad S_2 = \begin{pmatrix} 1 & r_1 \\ r_2 & 1 \end{pmatrix}.$$

We prove the result for S_1 only, since the argument for S_2 is completely analogous. Now, for S_1 to be an \mathcal{S} -matrix there must exist an $(u_1, u_2)' > 0$ such that,

$$u_1 + u_2 r_2 > 0 \tag{3.2}$$

$$u_1 r_1 + u_2 > 0. \tag{3.3}$$

First suppose $r_1, r_2 > 0$. Then any $(u_1, u_2)' > 0$ satisfies (3.2) and (3.3). In the cases (i) $r_1 > 0, r_2 < 0$, (ii) $r_1 < 0, r_2 > 0$, and (iii) $r_1, r_2 < 0$, it can be checked that (3.2) and (3.3) holding for some positive u is equivalent to $r_1 r_2 < 1$. This last inequality obviously holds in cases (i) and (ii). It also holds in case (iii) because $1 + r_1 + r_2 > 0$ insures $r_1, r_2 \geq -1$ and at least one of them is strictly bigger than -1. Finally, if $r_1 = 0$ and/or $r_2 = 0$ then, for example $u = (1, 1)$ satisfies (3.2) and (3.3).

□

Having now dispatched with the first line in Figure 3.1, we present a lemma relating to the second line.

Lemma 7. *Let the data (θ, Γ, R) be rotationally symmetric and let R be non-singular and completely- \mathcal{S} . Then $R^{-1}\theta < 0$ is equivalent to $\theta_0 < 0$.*

Proof. Using Lemma 5 the condition $R^{-1}\theta < 0$ reduces to

$$(a + b + c)\theta_0 < 0.$$

The second part of Lemma 5 states that $(a + b + c) = [1 + r_1 + r_2]^{-1}$. Hence, we can rewrite the condition as

$$R^{-1}\theta = \frac{\theta_0}{1 + r_1 + r_2} < 0. \tag{3.4}$$

By Lemma 6, the completely-S condition is equivalent to $1 + r_1 + r_2 > 0$. Given this inequality, (3.4) is clearly equivalent to $\theta_0 < 0$. \square

Now we proceed to results involving the last two lines in Figure 3.1.

Lemma 8. *Let the data (θ, Γ, R) be rotationally symmetric. Suppose further that R is non-singular, completely-S, and $R^{-1}\theta < 0$. Then the SRBM associated with (θ, Γ, R) is stable iff $r_1 + r_2 < 2$.*

Proof. Our proof relies on the results in [5] as depicted in Figure 3.1. The assumptions of the lemma place us in the lower half of the figure. To further partition the proof, we divide the (r_1, r_2) plane into four regions:

- $C_1 = \{(r_1, r_2) \in \mathbb{R}^2 : r_1 < 1, r_2 > 1\}$
- $C_2 = \{(r_1, r_2) \in \mathbb{R}^2 : r_1 > 1, r_2 < 1\}$
- $C_3 = \{(r_1, r_2) \in \mathbb{R}^2 : r_1 \geq 1, r_2 \geq 1\} \setminus (1, 1)$
- $C_4 = \{(r_1, r_2) \in \mathbb{R}^2 : r_1 \leq 1, r_2 \leq 1\} \setminus (1, 1)$.

We do not include the completely-S condition that $r_1 + r_2 > -1$ in this partitioning scheme because the condition is not employed directly in the algebraic arguments below. Under our assumption $R^{-1}\theta < 0$, the definitions of C_1 and C_2 coincide with the Bramson et al. [5] definitions given here. Furthermore, note that if $(r_1, r_2) \in C_1 \cup C_2$ then $(\theta, R) \in C$.

The one point of the plane not included in the union of these regions is $r_1 = r_2 = 1$. The matrix R is singular in this case, which violates the assumption of the

lemma. Notice that the line $r_1 + r_2 = 2$ bisects $C_1 \cup C_2$ and that C_3 lies entirely above this line and C_4 entirely below this line.

Case 1: Suppose $(r_1, r_2) \in C_1 \cup C_2$. In this case, stability of the SRBM is equivalent to $\beta(\theta, R) < 1$. Now, when $(r_1, r_2) \in C_1$ we have,

$$\beta(\theta, R) = \left(\frac{1 - r_2}{r_1 - 1} \right)^3.$$

Since the numerator and denominator are both negative for $(r_1, r_2) \in C_1$, the condition $\beta(\theta, R) < 1$ is equivalent to $1 - r_2 > r_1 - 1$, which holds iff $r_1 + r_2 < 2$.

Next, when $(r_1, r_2) \in C_2$,

$$\beta(\theta, R) = \left(\frac{1 - r_1}{r_2 - 1} \right)^3.$$

Again, the numerator and denominator in the last expression are both negative for $(r_1, r_2) \in C_2$. Therefore, $\beta(\theta, R) < 1$ is equivalent $1 - r_1 > r_2 - 1$, which also holds iff $r_1 + r_2 < 2$.

So, for all of Case 1, $r_1 + r_2 < 2$ is necessary and sufficient for stability.

Case 2: Suppose $(r_1, r_2) \in C_3 \cup C_4$. In this case stability of the SRBM is equivalent to the nonexistence of a divergent solution to the LCP.

Case 2a: We examine the case $(r_1, r_2) \in C_3$. Since $r_1 + r_2 > 2$ for all points in C_3 we need to show instability for data in this region. In the LCP, let $u = (-\theta_0, 0, 0)'$ and $v = -\theta_0(0, r_1 - 1, r_2 - 1)'$. This is clearly a divergent solution to the LCP for any $(r_1, r_2) \in C_3$. Therefore the corresponding SRBM is never stable in this case.

Case 2b: We examine the case $(r_1, r_2) \in C_4$. Since $r_1 + r_2 < 2$ for all points in C_3 we need to show stability for data in this region.

Consider a solution u, v to the LCP. We show that there exist no divergent solutions for this case. If $u > 0$, then $v = 0$ and the solution is stable. If $u = 0$, then we must have $v = \theta < 0$ which is not an allowable LCP solution. So if there exists a divergent solution, either one term or two terms in $u = (u_1, u_2, u_3)'$ is positive. Suppose one term is positive and it is u_1 , which implies $v_1 = 0$. Then we have $v_1 = \theta_0 + u_1 = 0$ yielding $u_1 = -\theta_0$. Therefore, in this case the unique a solution to the LCP must be of the form $u = (-\theta_0, 0, 0)'$, $v = -\theta_0(0, r_1 - 1, r_2 - 1)'$, which violates the non-negativity condition of v . Exactly analogous arguments show that neither u_2 nor u_3 can be the positive term. So, there exist no LCP solutions in which only one term in u is positive.

Next, suppose that two terms of u are positive. Again, without loss of generality, suppose $u_1 > 0, u_2 > 0$, and $u_3 = 0$, which implies $v_1 = v_2 = 0$. From the LCP equations we have $u_1 + r_2 u_2 + \theta_0 = 0$ and $u_2 + r_1 u_1 + \theta_0 = 0$. Solving these yields:

$$u_1 = \frac{-\theta_0(1 - r_2)}{1 - r_1 r_2} \quad u_2 = \frac{-\theta_0(1 - r_1)}{1 - r_1 r_2}. \quad (3.5)$$

If $r_1 = 1$, then $r_2 < 1$ and these equations force $u_2 = 0$, which contradicts our assumption on u . Similarly, we cannot have $r_2 = 1$. So, we now assume that both r_1 and r_2 are strictly less than 1. In this case, the solution given in (3.5) implies that both u_1 and u_2 are positive. Once again using the LCP equations we obtain:

$$v_3 = -\theta_0 \cdot \frac{r_1 - r_1^2 + r_2 - r_2^2 + r_1 r_2 - 1}{1 - r_1 r_2}. \quad (3.6)$$

Note that $1 - r_1 r_2 > 0$, $-\theta_0 > 0$, and

$$r_1 - r_1^2 + r_2 - r_2^2 + r_1 r_2 - 1 \leq r_1 + r_2 - r_1 r_2 - 1 = -(1 - r_1)(1 - r_2) < 0,$$

Therefore, $v_3 < 0$ which violates the non-negativity condition in the LCP.

We have now demonstrated that no divergent LCP solutions exist when $(r_1, r_2) \in C_4$. So, any SRBM with data in this region is stable. \square

Lemmas 6 through 8 then imply simple existence and stability conditions for RS-SRBM in three dimensions.

Theorem 9. *Consider an SRBM in three dimensions with rotationally symmetric data (θ, Γ, R) . The necessary and sufficient conditions for existence and stability of such an SRBM are $\theta_0 < 0$ and $-1 < r_1 + r_2 < 2$.*

The results in [16], which we shall make use of in later sections, require that R be a \mathcal{P} -matrix. The next result shows that this is not a restriction in the rotationally symmetric case, given that we only study stable SRBM's.

Theorem 10. *Suppose R is rotationally symmetric and $r_1 + r_2 < 2$. Then R being completely- \mathcal{S} is equivalent to R being a \mathcal{P} -matrix.*

Proof. Lemma 6 states that R being completely- \mathcal{S} is equivalent to

$$r_1 + r_2 + 1 > 0. \tag{3.7}$$

By definition, the conditions

$$1 - r_1 r_2 > 0 \tag{3.8}$$

$$1 + r_1^3 + r_2^3 - 3r_1 r_2 > 0 \tag{3.9}$$

are necessary and sufficient for R to be a \mathcal{P} -matrix. We prove that (3.7) is equivalent to (3.8) and (3.9) by partitioning the possible values of r_1 and r_2 .

1. Suppose that either $r_1 = 0$ or $r_2 = 0$. We prove the case in which $r_2 = 0$, the other case is analogous. When $r_2 = 0$ (3.7) reduces to $r_1 + 1 > 0$, (3.8) is trivially satisfied, and (3.9) reduces to $r_1^3 + 1 > 0$. The first inequality is equivalent to the last, establishing the result for this case.
2. Suppose $r_1, r_2 > 0$. It is easy to see that (3.7) always holds in this case. Furthermore, $r_1 + r_2 < 2$ implies

$$\left(\frac{r_1 + r_2}{2}\right)^2 < 1.$$

The arithmetic-geometric mean (AGM) inequality gives

$$r_1 r_2 \leq \left(\frac{r_1 + r_2}{2}\right)^2, \quad (3.10)$$

and thus (3.8) always holds. Invoking the AGM inequality again yields

$$r_1 r_2 = \sqrt[3]{r_1^3 r_2^3} \leq \frac{1 + r_1^3 + r_2^3}{3}.$$

Recall that equality in the AGM inequality holds iff the three terms are equal. Equality of the terms in this case implies $r_1 = r_2 = 1$ which is not possible due to $r_1 + r_2 < 2$. Therefore (3.9) automatically holds.

3. Suppose $r_1, r_2 < 0$. Note that

$$1 + r_1^3 + r_2^3 - 3r_1 r_2 = (r_1 + r_2 + 1)(1 + r_1^2 + r_2^2 - r_1 - r_2 - r_1 r_2) \quad (3.11)$$

and

$$1 + r_1^2 + r_2^2 - r_1 - r_2 - r_1 r_2 > 0,$$

when $r_1, r_2 < 0$. Therefore, in this case, (3.7) and (3.9) are equivalent and we need only show that (3.7) implies (3.8). Note then that $r_1 + r_2 + 1 > 0$, implies that $r_1 > -1$ and $r_2 > -1$. Given that both r_1 and r_2 are also negative this yields $r_1 r_2 < 1$.

4. Suppose $r_1 > 0$ and $r_2 < 0$ (the case $r_1 < 0$, $r_2 > 0$ is analogous). It is obvious that (3.8) always holds in this case and so we need only show that (3.7) and (3.9) are equivalent. Consider again the last term in (3.11):

$$1 + r_1^2 + r_2^2 - r_1 - r_2 - r_1 r_2 = (r_1 - r_2)^2 - (r_1 - 1)(1 - r_2).$$

Note that when $r_1 < 1$ this term is positive as can be seen from the right-hand side above. When $r_1 \geq 1$ we have $r_1 - r_2 > r_1 - 1 \geq 0$ and $r_1 - r_2 \geq 1 - r_2 > 0$ and again the right-hand side above is clearly positive. This fact implies that (3.7) and (3.9) are equivalent, as argued in Case 3.

□

Chapter 4

Optimal Paths in the Variational Problem

4.1 Preliminaries

In this section we establish some notation and review the properties pertaining to optimal paths. As much as possible we use notation which is consistent with either [2] or [16]. Many of our results rely on algebraic expressions given in [16]. First, we give expressions for the optimal costs of various types of paths.

Set $I = \{1, 2, \dots, d\}$ and for $K \subset I$ define the face associated with K as follows:

$$F_K = \{v \in \mathbb{R}_+^d : v_i = 0 \text{ for all } i \in K\}.$$

When $d = 3$, if $|K| = 2$ then F_K is an axis and if $|K| = 1$ then F_K is a 2-dimensional face.

Definition 9. We define the following costs.

1. (Direct Path Cost) For $v \in \mathbb{R}_+^d$, set

$$\tilde{J}_0(v) = \inf_{T \geq 0} \inf_{x \in \mathcal{H}^d, x(T)=v} \frac{1}{2} \int_0^T \| \dot{x}(t) - \theta \|^2 dt.$$

2. (One-piece Reflected Path Cost) For $K \subset I$ and $v \in F_K$, set

$$\tilde{\mathcal{J}}_K(v) = \inf_{T \geq 0} \inf_{x \in \mathcal{H}^d, \psi(x)(T)=v} \frac{1}{2} \int_0^T \|\dot{x}(t) - \theta\|^2 dt.$$

3. (Two-Piece Path via Face F_K) Let $d = 3$ and $|K| \leq 2$. For $v \in \mathbb{R}_+^3$, set

$$\tilde{\mathcal{J}}_K^2(v) = \inf_{w \in F_K} (\tilde{\mathcal{J}}_K(w) + \tilde{\mathcal{J}}_0(v - w)).$$

4. (Two-Piece Path via an Axis). Let $d = 3$ and $|K| = 2$. For $i \in K$ and $v \in F_i$, set

$$\tilde{\mathcal{J}}_{K,i}^2(v) = \inf_{w \in F_K} (\tilde{\mathcal{J}}_K(w) + \tilde{\mathcal{J}}_i(v - w)).$$

5. (Three-Piece Gradual Escape Path) Let $d = 3$, $|K| = 2$. For $i \in K$ and $v \in \mathbb{R}_+^3$, set

$$\tilde{\mathcal{J}}_{K,i}^3(v) = \inf_{u \in F_i} (\tilde{\mathcal{J}}_{K,i}^2(u) + \tilde{\mathcal{J}}_0(v - u)).$$

Each cost above corresponds to the cost for an optimal path of a certain type, as denoted in each item in the list. These costs, and the associated paths, are the building blocks for constructing paths which are optimal in the original variational problem.

In [2], the authors established various properties of optimal paths that hold in all dimensions. The first three items in Lemma 12 restate those properties. We add a fourth property for RSVPs and MSVPs in three dimensions. These properties are frequently used to establish results in subsequent sections. The first three parts are proved in [2], the fourth result is evident using symmetry. We state and prove a simple extension to the convexity property (see Lemma 11). The convexity property below

implies that direct paths within a face should have constant velocity and direction. The extension shows that this also is true for reflected paths.

Lemma 11 (Reflected Convexity). *Consider a section of a feasible triple (x, y, z) in which the path z consists of segments $\overline{v^1 v^2}$ and $\overline{v^2 v^3}$, with $v^1, v^2, v^3 \in F_j$ where $j \in \{1, 2, 3\}$. Suppose that $\overline{v^1 v^2}$ is a reflected segment and $\overline{v^2 v^3}$ is direct. Then there exists a linear reflected path from v_1 to v_3 whose cost is no greater than the original path.*

Proof. Without loss of generality, assume that $j = 1$. Let $(x^1(t), y^1(t), z^1(t))$ be the triple corresponding to the segment $\overline{v^1 v^2}$ with $T = T^1$. Similarly, let $(x^2(t), y^2(t), z^2(t))$ be the triple corresponding to $\overline{v^2 v^3}$ with $T = T^2$. Note that $(x^1(t), y^1(t), z^1(t)) = (\dot{x}^1, \dot{y}^1, \dot{z}^1)t$ and $(x^2(t), y^2(t), z^2(t)) = (\dot{x}^2, \dot{y}^2, \dot{z}^2)t$. Further denote $\dot{x}^1 = (x_1^1, x_2^1, x_3^1)'$. Similar notation is used for the other variables. Notice that $\dot{y}^1 = (y_1^1, 0, 0)'$ and $\dot{y}^2 = 0$.

By our assumptions on the segments, we have $\dot{x}^1 + R\dot{y}^1 = \dot{z}^1$, $\dot{x}^2 = \dot{z}^2$, $\dot{z}_1^1 = 0$, $\dot{x}_1^1 < 0$ and $\dot{x}_1^2 = 0$. By translation, we set $z^1(T^1) = v^2 - v^1$ and $z^2(T^2) = x^2(T^2) = v^3 - v^2$. Also, define points $u^2 = v^1 + x^1(T^1)$ and $u^3 = u^2 + x^2(T^2)$. Notice that these two points are not in the interior of the octant. Based on convexity,

$$\tilde{J}_0(u^3 - u^2) + \tilde{J}_0(u^2 - v^1) \geq \tilde{J}_0(u^3 - v^1).$$

Let $x^3(t)$ be optimal to $\tilde{J}_0(u^3 - v^1)$ with corresponding $T = T^3$, where $x^3(t) = \dot{x}^3 t$. It is clear that $\dot{x}^3 T^3 = u^3 - v^1 = \dot{x}^1 T^1 + \dot{x}^2 T^2$. Define $\dot{y}^3 = \frac{\dot{y}^1 T^1}{T^3}$ and $y^3(t) = \dot{y}^3 t$. Also define $z^3(t) = z^3(t) + R\dot{y}^3(t)$. So $z^3(T^3) = v^3 - v^1$. Thus $(x^3(t), y^3(t), z^3(t))$ is a

feasible triple for $\tilde{\mathcal{J}}_1(v^3 - v^1)$. Therefore,

$$\begin{aligned}\tilde{\mathcal{J}}_1(v^3 - v^1) &\leq \frac{1}{2} \int_0^{T^3} \|\dot{x}^3(t) - \theta\|^2 dt = \tilde{\mathcal{J}}_0(u^3 - v^1) \leq \tilde{\mathcal{J}}_0(u^3 - u^2) + \tilde{\mathcal{J}}_0(u^2 - v^1) \\ &= \tilde{\mathcal{J}}_1(v^2 - v^1) + \tilde{\mathcal{J}}_0(v^3 - v^2),\end{aligned}$$

which establishes the result. □

Lemma 12. 1. (*Optimality of Linear Paths via Convexity*) Let g be a convex function on \mathbb{R}^d , and $x \in \mathcal{H}^d$. Then for $t_1 < t_2$,

$$\int_{t_1}^{t_2} g(\dot{x}(t)) dt \geq \int_{t_1}^{t_2} g\left(\frac{x(t_2) - x(t_1)}{t_2 - t_1}\right) dt.$$

This implies that a (one-piece) linear path minimizes the unconstrained variational problem.

2. (*Scaling*) Consider a variational problem with $v \in \mathbb{R}_+^d$. For $\forall k > 0$, $I(kv) = kI(v)$. Furthermore, if (x, y, z) is the optimal triple for v and $\hat{x}, \hat{y}, \hat{z}$ is the optimal triple for kv , then $\hat{x}(t) = kx(t/k)$, $\hat{y}(t) = ky(t/k)$, $\hat{z}(t) = kz(t/k)$.

3. (*Merging Paths*) Let (x_1, y_1, z_1) be an R -regulation triple on $[0, t_1]$ with $z_1(0) = 0$ and $z_1(t_1) = w$ and (x_2, y_2, z_2) be an optimal triple on $[s_2, t_2]$ with $z_2(s_2) = w$ and $z_2(t_2) = v$. Suppose both x_1 and x_2 are absolutely continuous. Define

$$\begin{aligned}z(t) &= \begin{cases} z_1(t) & \text{for } 0 \leq t \leq t_1, \\ z_2(t - t_1 + s_2) & \text{for } t_1 \leq t \leq t_1 + t_2 - s_2, \end{cases} \\ x(t) &= \begin{cases} x_1(t) & \text{for } 0 \leq t \leq t_1, \\ x_2(t - t_1 + s_2) & \text{for } t_1 \leq t \leq t_1 + t_2 - s_2, \end{cases}\end{aligned}$$

$$y(t) = \begin{cases} y_1(t) & \text{for } 0 \leq t \leq t_1, \\ y_2(t - t_1 + s_2) & \text{for } t_1 \leq t \leq t_1 + t_2 - s_2, \end{cases}$$

and $s = t_1 + t_2 - s_2$. Then (x, y, z) is an R -regulation triple on $[0, s]$ with $z(0) = 0$ and $z(s) = v$.

4. (*Symmetric Terminal Points*) Consider an RSVP. If $v_1 = (a, b, c)$, $v_2 = (b, c, a)$, $v_3 = (c, a, b)$ with $a, b, c \geq 0$, then $I(v_1) = I(v_2) = I(v_3)$. Furthermore, each optimal path to one of these points is rotationally symmetric translation of an optimal path to one of the other points. For an MSVP case, let $v'_1 = (b, a, c)$, $v'_2 = (c, b, a)$, $v'_3 = (a, c, b)$, then $I(v_1) = I(v_2) = I(v_3) = I(v'_1) = I(v'_2) = I(v'_3)$.

4.2 Eliminating Bad Faces in RSVPs

The next result is one of the key results in this dissertation, since it allows us to eliminate entire categories of paths by eliminating paths whose penultimate pivot point is on a “bad face.” Below, the distance between a face and a point is the standard Euclidean distance from a point to the associated face.

Theorem 13 (Bad Faces). *Consider a variational problem with terminal point $v \in \text{int}(\mathbb{R}_+^3)$ and consider an optimal triple (x, y, z) to v . Let w be the last point of z which is not in $\text{int}(\mathbb{R}_+^3)$. Then*

- (a) *If the variational problem is an RSVP, then there exists an optimal path for which w is in one of the two nearest faces to v .*

(b) *If the variational problem is an MSVP, then there exists an optimal path for which w is in the nearest face to v .*

Proof. Let the terminal point be $v = (v_1, v_2, v_3)$, and without loss of generality, assume $v_3 \geq v_2 \geq v_1 > 0$. Define $u^1 = (0, a, b)$, $u^2 = (b, 0, a)$, $u^3 = (a, b, 0)$ and $u^4 = (0, b, a)$. Furthermore, we assume that we cannot have both $a = 0$ and $b = 0$.

First, we want to compare the optimal cost from u^i to v for various values of i . Of course, by convexity (Lemma 12, part 1), the optimal path from any u^i to v must be a linear path. Now, recall that

$$\tilde{J}_0(v - u^i) = \|\theta\| \|v - u^i\| - \langle \theta, v - u^i \rangle,$$

for $i \in \{1, 2, 3, 4\}$. It can be checked that

$$\langle \theta, v - u^i \rangle = \theta_0 \sigma^{-2} (2\gamma_1 + \gamma_0) (v_1 + v_2 + v_3 - a - b).$$

Hence this portion of the cost is independent of i . So it is sufficient to analyze $\|v - u^i\|$ or, equivalently, $\|v - u^i\|^2$. Note then that

$$\|v - u^i\|^2 = \langle v, v \rangle + \langle u^i, u^i \rangle - 2\langle v, u^i \rangle,$$

where $\langle u^i, u^i \rangle = \sigma^{-2}[(a^2 + b^2)\gamma_0 + 2ab\gamma_1]$. Therefore, the first two terms in $\|v - u^i\|^2$ are also independent of i . So, finally, we have

$$\langle v, u^1 - u^3 \rangle = \sigma^{-2}[(\gamma_0 - \gamma_1)(v_3 - v_2)b + (\gamma_0 - \gamma_1)(v_2 - v_1)a] \geq 0,$$

where the inequality is due to our assumption on v and Lemma 4. This of course implies that $\langle v, u^1 \rangle \geq \langle v, u^3 \rangle$ with equality iff $(v_3 - v_2)b + (v_2 - v_1)a = 0$. Therefore

we have

$$\tilde{J}_0(v - u^3) \geq \tilde{J}_0(v - u^1). \quad (4.1)$$

Now, let w be the last point which is not in the interior of the octant, for an optimal path with terminal point v . By convexity, the segment \overline{wv} must be linear. Suppose then that w is in F_3 . If $v_3 \neq v_2$ then F_3 is the furthest face from v . Thus w must be of the form of u^3 and accordingly we take $w = u^3 = (a, b, 0)$. Now, consider the point $u^1 = (0, a, b)$. Note that the optimal cost from the origin to u^3 and the optimal cost from the origin to u^1 must be equal due to rotational symmetry. By the merging and convexity properties of Lemma 12, to establish (a) it suffices to show that the optimal cost from u^1 to v using a direct path is less than or equal the cost from u^3 to v via a direct path. This result was already demonstrated, as seen in (4.1).

At this point some discussion may be needed to see that part (a) of the theorem has been proved. Suppose first that $v_3 > v_2 > v_1 > 0$. Then F_3 is the unique furthest face from v . In this case we can strengthen the conclusion of part (a). In particular, the last boundary point in an optimal path must emanate from one of the two nearest faces. Next, if $v_2 = v_3$ then all three faces can be classified as “one of the two nearest” and the statement of (a) holds by default. Finally, if $v_3 > v_2 = v_1 > 0$ there are two cases. If $b \neq 0$, then u^3 is in the interior of F_3 and there must exist a strictly cheaper path through u^1 . If $b = 0$, then the cost of the paths through u^3 and u^1 are the same. Either path is considered to be via F_1 (albeit on the boundary) which is one of the two nearest faces to v . Hence, the result in (a) is still valid.

We now address part (b) of the theorem. First, it can be checked that

$$\langle v, u^4 - u^2 \rangle = \sigma^{-2}[b(v_2 - v_1)(\gamma_0 - \gamma_1)] \geq 0,$$

with equality if $b = 0$ or $v_1 = v_2$. Using the calculations from the RSVP case, we have

$$\tilde{J}_0(v - u^2) \geq \tilde{J}_0(v - u^4). \quad (4.2)$$

By mirror symmetry, the optimal cost from the origin to u^2 and the optimal cost from the origin to u^4 must be equal.

The remainder of the proof is similar to the part (a) argument. Again, let w be the last point which is not in the interior of the octant, for an optimal path with terminal point v . Suppose first that w is in F_3 . Unless $v_1 = v_2 = v_3$ (in which case the result holds trivially), then F_3 is one of the two furthest faces from v . Recall that an MSVP is also an RSVP, so we can apply part (a) of the theorem to conclude that there must exist an optimal path to v with $w \in F_2$. Without loss of generality, assume then that $w = u^2 = (b, 0, a)$.

However, by (4.2) the optimal cost from u^4 to v using a direct path is less than or equal the cost from u^2 to v via a direct path. Hence, there exists a path for which u^4 is last point on the boundary of the octant, with lower (or equal) cost to the path through u^2 .

As in part (a), there are some special cases in part (b), specifically, when $v_1 = v_2$ or $b = 0$. If $v_1 = v_2$ then both F_1 and F_2 are considered the “nearest face” and the statement holds immediately by applying part (a). If $v_2 > v_1$ and $b \neq 0$,

then there exists a strictly cheaper path through u^4 . If $v_2 > v_1$ and $b = 0$, then u^4 is considered to be in F_1 and again the result holds. \square

The easiest way of rephrasing the RSVP result is as follows. Consider a terminal point v with a unique farthest face. Then the last linear segment in an optimal path cannot emanate from the interior of the farthest face. Similarly, for an MSVP with a unique nearest face to the terminal point v , the last linear segment must emanate from the nearest face.

Note that the results in Theorem 13 are proved only for v in the interior of the octant. The arguments in the proof of the theorem lead immediately to the following extensions for terminal points on the boundary of the octant.

Remark 1. When $v_1 = 0$ and $v_2 > 0$, v is in the interior of F_1 . The first part of Theorem 13 holds in the following sense: For an RSVP, there exists an optimal path whose last segment does not emanate from the interior of F_3 . Furthermore, the last segment can not originate from $F_{2,3}$ although it may originate from $F_{1,3}$.

Remark 2. When $v_1 = v_2 = 0$ and $v_3 > 0$, v is on the axis $F_{1,2}$. Again, the first part of Theorem 13 holds. In particular, there exists an optimal path whose last segment does not emanate from the interior of the farthest face, which is F_3 in this case.

Finally, we believe that the results of this section can be generalized to higher dimensional RSVPs and MSVPs with minor modifications to the proofs.

4.3 Further Optimal Path Characterizations

Our eventual goal is to show that optimal paths in three dimensions can be of only two types: gradual paths and classic spirals. Demonstrating this requires the establishment of a number of properties for paths with a finite or infinite number of linear segments. The results in this section are related to paths with a finite number of segments, although some of these properties are used later on to establish characterizations for paths with an infinite number of segments.

In various proofs in this section it is useful to consider paths (and the corresponding costs), which are feasible, but not necessarily optimal. Therefore, we introduce the following definition.

Definition 10. (Cost of a Feasible Path) Given a one-piece feasible R-regulated triple (x, y, z) from u to a terminal point v , define the corresponding cost along that path to be

$$H_{y,z}(v - u) = \frac{1}{2} \int_0^T \| \dot{x}(t) - \theta \|^2 dt,$$

where $z(T) = v - u$.

The next several results provide detailed characterizations of optimal paths. Unfortunately, the overall connection will not be apparent until we bring them together to prove the main results.

Lemma 14 (The Switchback Lemma). *Consider a VP with $\Gamma = I$. Let $v^1, v^4 \in \text{int}(F_1)$ and $v^2, v^3 \in \text{int}(F_2)$. Then the path from v^1 to v^4 consisting of the following linear segments is strictly suboptimal: a direct segment from v^1 to v^2 , a reflected segment from v^2 to v^3 , a direct segment from v^3 to v^4 .*

Proof. Let $v^1 = (0, v_2^1, v_3^1)$, $v^2 = (v_1^2, 0, v_3^2)$, $v^3 = (v_1^3, 0, v_3^3)$, and $v^4 = (0, v_2^4, v_3^4)$. Assume first that $v_1^2 \geq v_1^3$. Define $\tilde{v}^2 = (v_1^2 - v_1^3, 0, v_3^2)$ and $\tilde{v}^3 = (0, 0, v_3^3)$ which are both in F_2 . Consider a new path from v^1 to v^4 as follows: a direct segment from v^1 to \tilde{v}^2 , a reflected segment from \tilde{v}^2 to \tilde{v}^3 , a direct segment from \tilde{v}^3 to v^4 . We show that the new path has a strictly lower cost than the original path. Notice that $v^3 - v^2 = \tilde{v}^3 - \tilde{v}^2$ so it suffices to compare $\tilde{J}_0(v^2 - v^1) + \tilde{J}_0(v^4 - v^3)$ with $\tilde{J}_0(\tilde{v}^2 - v^1) + \tilde{J}_0(v^4 - \tilde{v}^3)$. By definition

$$\tilde{J}_0(v^2 - v^1) + \tilde{J}_0(v^4 - v^3) = \|\theta\|(\|v^2 - v^1\| + \|v^4 - v^3\|) - \langle \theta, v^2 - v^1 + v^4 - v^3 \rangle$$

and

$$\tilde{J}_0(\tilde{v}^2 - v^1) + \tilde{J}_0(v^4 - \tilde{v}^3) = \|\theta\|(\|\tilde{v}^2 - v^1\| + \|v^4 - \tilde{v}^3\|) - \langle \theta, \tilde{v}^2 - v^1 + v^4 - \tilde{v}^3 \rangle.$$

It is easy to check that

$$\langle \theta, v^2 - v^1 + v^4 - v^3 \rangle = \langle \theta, \tilde{v}^2 - v^1 + v^4 - \tilde{v}^3 \rangle$$

so it is enough to compare $\|v^2 - v^1\| + \|v^4 - v^3\|$ with $\|\tilde{v}^2 - v^1\| + \|v^4 - \tilde{v}^3\|$. Now when $\Gamma = I$, we have

$$\begin{aligned} & (\|v^2 - v^1\| + \|v^4 - v^3\|) - (\|\tilde{v}^2 - v^1\| + \|v^4 - \tilde{v}^3\|) \\ &= \sqrt{p + (v_1^2)^2} + \sqrt{q + (v_1^3)^2} - \sqrt{p + (v_1^2 - v_1^3)^2} - \sqrt{q} > 0 \end{aligned}$$

Here $p = (v_2^1)^2 + (v_3^2 - v_3^3)^2 > 0$ and $q = (v_2^4)^2 + (v_3^4 - v_3^3)^2 > 0$. Thus, the newly constructed path has a strictly lower cost. If $v_1^2 < v_1^3$ then re-define $\tilde{v}^2 = (0, 0, v_3^2)$ and $\tilde{v}^3 = (v_1^3 - v_1^2, 0, v_3^3)$. The proof of the corresponding result for this case is analogous to the first case. \square

This result is the key to showing that “exotic” paths which seem intuitively “bad” are indeed suboptimal. In particular, it shows that paths which switch back and forth between two faces are not cost effective. Analogous arguments show that the lemma holds for any pair of two-dimensional faces.

The next result is important in establishing the optimality of gradual paths. In this and later proofs, we use the standard notation $e_3 = (0, 0, 1)$.

Lemma 15. *Consider an RSVP with $\Gamma = I$ and $r_2 \geq 0$. Let $v^1 = (0, v_2^1, v_3^1)$ and $v^2 = (v_1^2, 0, v_3^2)$, such that $v^1 \in \text{int}(F_1)$ and $v^2 \in \text{int}(F_2)$. Then the path from v^1 to e_3 consisting of the following linear segments is strictly suboptimal: a direct segment from v^1 to v^2 and a reflected segment from v^2 to e_3 .*

Proof. Define $\tilde{v}^2 = (0, 0, v_3^2)$. We show that

$$\tilde{J}_0(v^2 - v^1) + \tilde{J}_2(e_3 - v^2) > \tilde{J}_0(\tilde{v}^2 - v^1) + \tilde{J}_2(e_3 - \tilde{v}^2),$$

implying that there exists a better path from v^1 to e_3 , via \tilde{v}^2 .

Suppose (x^1, y^1, z^1) is an optimal triple from v^2 to e_3 with corresponding time T^1 , and let (x^2, y^2, z^2) be the optimal triple from v^1 to v^2 with corresponding time T^2 (since this path is direct $x^2 = z^2$). Set $(x^1(t), y^1(t), z^1(t)) = (\dot{x}^1, \dot{y}^1, \dot{z}^1)t$, $x^2(t) = \dot{x}^2 t$, with $\dot{z}^1 = (z_1^1, z_2^1, z_3^1)'$. Notice that $\dot{y}^1 = (0, y_2^1, 0)'$ and $z_2^1 = 0$. Let $\tilde{z}^1(t) = t(0, 0, z_3^1)'$ and $\tilde{x}^1(t) = t(-r_2 y_2^1, -y_2^1, x_3^1)'$. It can be checked that $(\tilde{x}^1, y^1, \tilde{z}^1)$ is a feasible triple from \tilde{v}^2 to e_3 with $\tilde{T}^1 = T^1$. Similarly, setting $\tilde{x}^2(t) = t(0, x_2^2, x_3^2)'$ yields the feasible triple $(\tilde{x}^2, 0, \tilde{x}^2)$ from v^1 to \tilde{v}^2 , with $\tilde{T}^2 = T^2$.

Using the paths defined above we have:

$$\tilde{J}_2(e_3 - v^2) = \frac{1}{2}T^1[(-z_1^1 - r_2y_2^1 - \theta_0)^2 + (-y_2^1 - \theta_0)^2 + (z_1^3 - r_1y_2^1 - \theta_0)^2]$$

and

$$\tilde{J}_2(e_3 - \tilde{v}^2) \leq \frac{1}{2}T^1[(-r_2y_2^1 - \theta_0)^2 + (-y_2^1 - \theta_0)^2 + (z_1^3 - r_1y_2^1 - \theta_0)^2],$$

where the inequality is due to the fact that $(\tilde{x}^1, y^1, \tilde{z}^1)$ need not be optimal.

Recall that $\dot{z}^1 T^1 = e_3 - v^2$. Finally, we expand the direct path costs similarly and compute:

$$\begin{aligned} & \tilde{J}_0(v^2 - v^1) + \tilde{J}_2(e_3 - v^2) - \tilde{J}_0(\tilde{v}^2 - v^1) - \tilde{J}_2(e_3 - \tilde{v}^2) \\ & \geq \frac{1}{2}T^1 \left[\left(-\frac{v_1^2}{T^1} - r_2y_2^1 - \theta_0 \right)^2 - (-r_2y_2^1 - \theta_0)^2 \right] + \frac{1}{2}T^2 \left[\left(\frac{v_1^2}{T^2} - \theta_0 \right)^2 - (-\theta_0)^2 \right] \\ & = \frac{1}{2} \left[\frac{(v_1^2)^2}{T^1} + \frac{(v_1^2)^2}{T^2} + 2r_2y_2^1v_1^2 \right]. \end{aligned}$$

Since $r_2 \geq 0$ and v_1^2 can be assumed to be positive, the last term is strictly positive, establishing the result. (If $v_1^2 = 0$ then the theorem holds trivially by convexity.) \square

In general, we apply this result under the condition that $r_1, r_2 \geq 0$. By symmetry it is easily seen that the result applied to rotational variations of the paths involved in the result.

Lemma 16. *Consider an RSVP with $v, \bar{v} \in \mathbb{R}_+^3$, where $v = (0, v_1, v_2)$ and $\bar{v} = (v_1, 0, v_2)$. If $r_1 \geq r_2$, $v_2 \geq v_1$, then*

$$\tilde{J}_1(v) \geq \tilde{J}_2(\bar{v}).$$

Proof. Let $(x^*(t), y^*(t), z^*(t))$ be an optimal triple corresponding to $\tilde{J}_1(v)$, and let T^* be the corresponding optimal time. It is clear that $\dot{z}^*(t)$ and $\dot{y}^*(t)$ are constant functions due to the convexity property of Lemma 12. Thus, we set $z^* := \dot{z}^*(t) = (0, z_1^*, z_2^*)'$ and $y^* = \dot{y}^*(t) = (y_1^*, 0, 0)'$. Therefore, $\dot{x}^*(t) = \dot{z}^* - R\dot{y}^*$ and z^* satisfies $z_1^* T^* = v_1$, and $z_2^* T^* = v_2$. It is clear that $z_1^* \leq z_2^*$ since $v_1 \leq v_2$.

Setting $\dot{\bar{z}}(t) = \bar{z} = (z_1^*, 0, z_2^*)'$, $\dot{\bar{y}}(t) = \bar{y} = (0, y_1^*, 0)'$ and $\dot{\bar{x}}(t) = \dot{\bar{z}} - R\dot{\bar{y}}$, we note that $(\bar{x}(t), \bar{y}(t), \bar{z}(t))$ is a feasible one-piece triple from the origin to \bar{v} where $z(\cdot) \in F_2$ and T^* is the corresponding time for this path to reach \bar{v} . Then

$$\tilde{J}_1(v) = \frac{1}{2} \|\dot{z}^*(t) - R\dot{y}^*(t) - \theta\|^2 T^* = \frac{1}{2} \|z^* - Ry^* - \theta\|^2 T^*.$$

On the other hand, since $(\bar{x}(t), \bar{y}(t), \bar{z}(t))$ is feasible,

$$\tilde{J}_2(\bar{v}) \leq H_{\bar{y}(t), \bar{z}(t)}(\bar{v}) = \frac{1}{2} \|\bar{z} - R\bar{y} - \theta\|^2 T^*.$$

So

$$\begin{aligned} \tilde{J}_1(v) - \tilde{J}_2(\bar{v}) &\geq \frac{1}{2} (\|z^* - Ry^* - \theta\|^2 - \|\bar{z} - R\bar{y} - \theta\|^2) T^* \\ &= \sigma^{-2} (r_1 - r_2) (\gamma_0 - \gamma_1) (z_2^* - z_1^*) y_1^* T^* \geq 0. \end{aligned}$$

The last inequality follows from our assumptions and because $\gamma_0 > \gamma_1$, due to Lemma 4. □

Our study of optimal path characterizations rests crucially on comparing the paths depicted in Figure 4.1. For paths with both a finite number of segments and an infinite number of segments, we wish to establish that the blue path is “cheaper” than the red path. In most instances it is difficult to establish this as a general property, so we provide sufficient conditions for this blue-path-red-path condition to

Figure 4.1: Red Path - Blue Path Comparison

hold. For specific numerical instances of an RSVP, these conditions can be verified easily. Furthermore, a combination of numerical and analytical arguments can be used to show that the conditions hold in general on R_f , defined below.

$$R_f = \{(r_1, r_2) \in \mathbb{R}_+^2 \mid r_1 > r_2, -1 < r_1 + r_2 < 2\}.$$

Condition 1. For an RSVP with reflection matrix R , $(r_1, r_2) \in R_f$ and

$$(1 + r_2^2)(1 + r_1^2 - r_2 - r_1 r_2)^2 \geq 2(r_1 r_2)^2(1 + r_1^2 + r_2^2 - r_1 - r_2 - r_1 r_2).$$

Condition 2. For an RSVP with reflection matrix R , $(r_1, r_2) \in R_f$ and at least one of the two inequalities below hold for each $(v_1, v_2, v_3) \in \mathbb{R}_+^3$:

$$[(1 + r_1 + r_2)T^* + r_1 v_2 + r_2(v_3 - 1)]^2 - (1 + r_1^2 + r_2^2)(2T^* v_1 - v_1^2) \geq 0.$$

$$4 \left[(1 + r_1 + r_2)T^* + \frac{1}{4}(r_1v_2 + r_2(v_3 - 1)) \right]^2 - (1 + r_1^2 + r_2^2) \left(9(T^*)^2 + 2T^*v_1 - v_1^2 - \frac{3}{4}[v_2^2 + (v_3 - 1)^2] \right) \geq 0,$$

where

$$T^* = \sqrt{\frac{v_1^2 + v_2^2 + (v_3 - 1)^2}{3}}.$$

These two conditions are required to prove the next two results.

Lemma 17. *Given an RSVP with $\Gamma = I$, $\theta_0 < 0$, and $r_1 > r_2 \geq 0$, define points $v = (v_1, 0, v'_3)$ and $v' = (0, v_2, v_3)$ with $v_i > 0$ for $i = 1, 2, 3$. Suppose further that $v_2 < v_3$ and $v_1 < 1$. Then*

(a) *If Condition 1 holds, then $\tilde{\mathcal{J}}_2(v) > \tilde{\mathcal{J}}_2(e_3)$.*

(b) *If Condition 2 holds, then $\tilde{\mathcal{J}}_0(v' - v) \geq \tilde{\mathcal{J}}_1(v' - e_3)$.*

Proof of Lemma 17. Part (a). The claim is that if Condition 1 holds, then $\tilde{\mathcal{J}}_2(v) > \tilde{\mathcal{J}}_2(e_3)$. Without loss of generality we set $v'_3 = 1$. So $v = (v_1, 0, 1)$. For all non-negative v_1 , define the function

$$G(v_1) := \tilde{\mathcal{J}}_2(v) = \|Av\| \|A\theta\| - \langle Av, A\theta \rangle,$$

where $A = I - R_2B$, $B = (R'_2R_2)^{-1}R'_2$, and $R_2 = (r_2, 1, r_1)'$. It can be checked that $G(\cdot)$ is strictly convex on $(0, 1)$. Therefore, to prove $\tilde{\mathcal{J}}_2(v) > \tilde{\mathcal{J}}_2(e_3)$ for $v_1 > 0$, it is enough to show that $\frac{\partial_+ G(v_1)}{\partial v_1} \Big|_{v_1=0} \geq 0$. Some algebra yields

$$\frac{\partial_+ G(v_1)}{\partial v_1} \Big|_{v_1=0} = \frac{1}{2} \frac{\|A\theta\|}{\|Ae_3\|} (A_{31} + A_{13}) - (A\theta)_1.$$

Note that $A_{31} + A_{13} \leq 0$ and $(A\theta)_1 \leq 0$ in R_f . So, to prove the non-negativity of the derivative, it is sufficient to show that

$$(A\theta)_1^2 \geq \frac{1}{4} \left[\frac{\|A\theta\|}{\|Ae_3\|} (A_{31} + A_{13}) \right]^2. \quad (4.3)$$

Next, we have

$$\left(\frac{\|A\theta\|}{\|Ae_3\|} \right)^2 = \frac{2(1 + r_1^2 + r_2^2 - r_1 - r_2 - r_1 r_2)}{1 + r_2^2} \theta_0^2,$$

and

$$(A\theta)_1 = \frac{1 + r_1^2 - r_2 - r_1 r_2}{1 + r_1^2 + r_2^2} \theta_0.$$

Plugging these equalities into (4.3) yields the condition

$$(1 + r_2^2)(1 + r_1^2 - r_2 - r_1 r_2)^2 \geq 2(r_1 r_2)^2(1 + r_1^2 + r_2^2 - r_1 - r_2 - r_1 r_2). \quad (4.4)$$

In summary, if (4.4) holds, then $\frac{\partial_+ G(v_1)}{\partial v_1}|_{v_1=0} \geq 0$ which in turn implies $\tilde{J}_2(v) > \tilde{J}_2(e_3)$.

Part (b). The claim is that if Condition 2 holds then $\tilde{J}_0(v' - v) \geq \tilde{J}_1(v' - e_3)$. Since $\tilde{J}_0(v' - v)$ and $\tilde{J}_1(v' - e_3)$ are both proportional to θ_0 it is enough to verify the case when $\theta_0 = -1$. We have that $\tilde{J}_0(v' - v) = \frac{1}{2} \|\dot{x}^*(t) - \theta\|^2 T^*$ where

$$T^* = \frac{\|v' - v\|}{\|\theta\|} = \sqrt{\frac{(v_1)^2 + (v_2)^2 + (v_3 - 1)^2}{3}}$$

and $x^*(t) = x^* t = t(x_1^*, x_2^*, x_3^*)'$ for $0 \leq t \leq T^*$. We construct a feasible reflected path in F_1 from e_3 to v' with a cost $H_{\tilde{y}, \tilde{z}}(v' - e_3)$ less than or equal to $\tilde{J}_0(v' - v)$. This construction then implies $\tilde{J}_0(v' - v) \geq \tilde{J}_1(v' - e_3)$. Below, we construct feasible triples with two different “speeds.” Of course, in the search for a lower cost path, one could examine all possible feasible speeds to generate a weaker sufficient condition than

that which appears in the lemma, but the cases we consider turn out to be sufficient for our purposes.

Denote one feasible triple from e_3 to v' by $(\tilde{x}(t), \tilde{y}(t), \tilde{z}(t))$ and \tilde{T} . Let $\tilde{T} = T^*$, $\tilde{z}(t) = \tilde{z}t = t(0, \tilde{z}_2, \tilde{z}_3)'$ and $\tilde{y}(t) = t(\tilde{y}_1, 0, 0)'$ for some $\tilde{y}_1 \geq 0$. It is clear that $\tilde{z}_2 = x_2^*$ and $\tilde{z}_3 = x_3^*$. The goal now is to determine if there exists a $\tilde{y}_1 \geq 0$ such that

$$\tilde{J}_0(v' - v) - H_{\tilde{y}, \tilde{z}}(v' - e_3) \geq 0.$$

Plugging in $\tilde{x}(t) = \tilde{z}(t) - R\tilde{y}(t)$, $x^*T^* = v' - v$, and writing $\bar{y} = \tilde{y}_1T^*$ we see that the inequality above is equivalent to

$$\begin{aligned} & (T^* - v_1)^2 + (T^* + v_2)^2 + (T^* + v_3 - 1)^2 \\ & - [(T^* - \bar{y})^2 + (T^* + v_2 - r_1\bar{y})^2 + (T^* + v_3 - 1 - r_2\bar{y})^2] \geq 0. \end{aligned} \tag{4.5}$$

Denote the second feasible triple by $(\hat{x}(t), \hat{y}(t), \hat{z}(t))$ and \hat{T} , where $\hat{y}(t) = t(\hat{y}_1, 0, 0)'$. This time however, set $\hat{T} = 4T^*$. As in the first case, we have $\hat{z}_1 = 0$, $\hat{z}_2 = \frac{x_2^*}{4}$ and $\hat{z}_3 = \frac{x_3^*}{4}$. Let $\check{y} = \hat{y}_1T^*$. The goal again is to determine if there exists a $\hat{y}_1 \geq 0$ such that

$$\tilde{J}_0(v' - v) - H_{\hat{y}, \hat{z}}(v' - e_3) \geq 0,$$

which is equivalent to

$$\begin{aligned} & (T^* - v_1)^2 + (T^* + v_2)^2 + (T^* + v_3 - 1)^2 \\ & - 4[(T^* - \check{y})^2 + (T^* + \frac{v_2}{4} - r_1\check{y})^2 + (T^* + \frac{v_3 - 1}{4} - r_2\check{y})^2] \geq 0. \end{aligned} \tag{4.6}$$

In summary, we claim that for given problem data and points v and v' if there exists a $\bar{y} \geq 0$ or $\check{y} \geq 0$ such that (4.5) or (4.6), respectively, is satisfied, then

the desired feasible path construction can be achieved. Notice that the left-hand sides (LHS) in these two equations are both concave, quadratic functions of \bar{y} and \check{y} , respectively. So to prove the desired inequalities, it is necessary that at least one of these two functions has a non-negative maximum which is achieved at a non-negative value.

In (4.5), the maximum value of the LHS is reached when

$$\bar{y}^* = \frac{(1 + r_1 + r_2)T^* + r_1v_2 + r_2(v_3 - 1)}{1 + r_1^2 + r_2^2}$$

and this maximum is achieved at a non-negative value when

$$[(1 + r_1 + r_2)T^* + r_1v_2 + r_2(v_3 - 1)]^2 - (1 + r_1^2 + r_2^2)(2T^*v_1 - v_1^2) \geq 0. \quad (4.7)$$

When $v_3 \geq 1$ it is easy to see that $\bar{y}^* \geq 0$. Considering now the LHS of (4.7) we have that

$$\text{LHS} \geq (1 + r_1 + r_2)^2(T^*)^2 - (1 + r_1^2 + r_2^2)(T^*)^2 = (T^*)^2(2r_1 + 2r_2 + 2r_1r_2) \geq 0.$$

So, when $v_3 \geq 1$, (4.5) is satisfied. The case when $v_3 < 1$ is more complicated and both (4.5) and (4.6) need to be checked. In this case we have

$$\begin{aligned} (1 + r_1 + r_2)T^* + r_1v_2 + r_2(v_3 - 1) &\geq \frac{(1 + r_1 + r_2)(v_1 + v_2 + (1 - v_3))}{3} \\ &+ r_1v_2 + r_2(v_3 - 1) \geq r_2(v_1 + v_2) + r_1v_2 \geq 0. \end{aligned}$$

So it is always true that the maximum \bar{y}^* is non-negative. Similarly for (4.6) the maximum value of the LHS is reached when

$$\check{y}^* = \frac{(1 + r_1 + r_2)T^* + \frac{1}{4}[r_1v_2 + r_2(v_3 - 1)]}{1 + r_1^2 + r_2^2}.$$

Again, through straightforward algebra, it can be established that $\tilde{y}^* \geq 0$. The maximum is achieved at a non-negative value when

$$4[(1 + r_1 + r_2)T^* + \frac{1}{4}(r_1v_2 + r_2(v_3 - 1))]^2 - (1 + r_1^2 + r_2^2)(9(T^*)^2 + 2T^*v_1 - v_1^2 - \frac{3}{4}[v_2^2 + (v_3 - 1)^2]) \geq 0. \quad (4.8)$$

Thus, we conclude that when either (4.7) or (4.8) holds we can construct the required feasible path and $\tilde{J}_0(v' - v) \geq \tilde{J}_1(v' - e_3)$.

□

Lemma 18. *Given an RSVP with $\Gamma = I$, $\theta_0 < 0$, and $r_1, r_2 \geq 0$, define points $v = (v_1, 0, v'_3)$ and $v' = (0, v_2, v_3)$ with $v_i > 0$ for $i = 1, 2, 3$. Then if Conditions 1 and 2 hold, the least cost two-piece path from the origin to v and from v to v' is not an optimal path to v' .*

Proof. Invoking the scaling property of Lemma 12, we assume without loss of generality that $v'_3 = 1$. When $v_2 \geq v_3$, the two-piece path through v is not optimal due to Theorem 13.

When $v_1 > 1$, by Theorem 13, the path described in the above lemma is not optimal.

Case 1. Consider then the case where $v_2 < v_3$ and $r_2 \geq r_1$ and set $\hat{v} = (0, v_1, 1)$. We claim that the optimal two-piece path through \hat{v} is strictly better than the optimal two-piece path through v . First, Lemma 16 gives $\tilde{J}_2(v) \geq \tilde{J}_1(\hat{v})$. In other words, the first segment of the path through \hat{v} has a lower (or equal) cost than the first segment through v' .

To compare the second segments, note that

$$\begin{aligned}\tilde{J}_0(v' - v) &= \|\theta\| \|v' - v\| - \langle \theta, v' - v \rangle \quad \text{and} \\ \tilde{J}_0(v' - \hat{v}) &= \|\theta\| \|v' - \hat{v}\| - \langle \theta, v' - \hat{v} \rangle.\end{aligned}$$

Furthermore, we have $\langle \theta, v' - v \rangle = \langle \theta, v' - \hat{v} \rangle$, and

$$\|v' - v\| = \sqrt{v_1^2 + v_2^2 + (v_3 - 1)^2} > \sqrt{(v_2 - v_1)^2 + (v_3 - 1)^2} = \|v' - \hat{v}\|.$$

Thus, $\tilde{J}_0(v' - v) > \tilde{J}_0(v' - \hat{v})$ and the result is established for this case.

Case 2. Suppose next that $v_2 < v_3$ and $v_1 \geq 1$ (with no restriction on r_1 and r_2). Let $\tilde{v} = (0, 1, v_1)$ and consider the two-piece path to v' via \tilde{v} . Again, we show that the optimal two-piece path through \tilde{v} is strictly better than the optimal two-piece path through v . By rotational symmetry $\tilde{J}_2(v) = \tilde{J}_1(\tilde{v})$. On the other hand $\langle \theta, v' - v \rangle = \langle \theta, v' - \tilde{v} \rangle$, and

$$\|v' - v\| = \sqrt{v_1^2 + v_2^2 + (v_3 - 1)^2} > \sqrt{(v_2 - 1)^2 + (v_3 - v_1)^2} = \|v' - \tilde{v}\|.$$

As in Case 1, this implies

$$\tilde{J}_0(v' - v) > \tilde{J}_0(v' - \tilde{v}),$$

which establishes the result for this case.

Case 3. The remaining case is when $v_2 < v_3$, $r_2 < r_1$, and $v_1 < 1$. Once again we find an alternate two-piece path to v' which has a lower cost. In this case, consider the two-piece path to v' via e_3 . If Conditions 1 and 2 hold, then Lemma 17 indicates that $\tilde{J}_2(v) > \tilde{J}_2(e_3)$ and $\tilde{J}_0(v' - v) \geq \tilde{J}_1(v' - e_3)$. This establishes the result for this case. \square

Note that Conditions 1 and 2 are only needed to establish the third case. It may be possible to replace these conditions by simpler expressions for special cases.

Next, we are now able to establish the result that there always exist gradual optimal paths to points on the boundary of the octant. It is important to note that the class of gradual paths do not include paths which traverse an axis and then cross the interior to a point on a two-dimensional face.

Theorem 19. *Consider an RSVP with $\Gamma = I$, $\theta_0 < 0$, $r_1, r_2 \geq 0$. Suppose Conditions 1 and 2 hold and that there exists an optimal path with a finite number of segments. Then:*

- (i) For any point on an axis there exists an optimal path consisting of a single segment; and*
- (ii) For any point on a two-dimensional face there exists an optimal gradual path, consisting of at most two segments.*

Proof. To prove the result we need to eliminate a large number of path types. In order to categorize these types, note that each type can be classified according to the endpoints of the linear segments. The endpoint of each piece can be on the interior of a two-dimensional face (F), on the interior of an axis (A), or the origin (O). In all the arguments below, we consider a path with a finite number of pieces, and thus a finite number of endpoints, which starts at a point v in the octant and terminates at the origin. Specifically, we label the endpoints in “reverse order.” Note that an endpoint cannot be in the interior of the octant due to the convexity property in Lemma 12.

Furthermore, note that the last point is always of type O and of course, this is the only position at which this type occurs.

Next, consider an endpoint of type F . There are three possibilities for the previous endpoint:

- The endpoint is on an axis A (either one of the two axes adjoining this face, or the remaining axis)
- The endpoint is on the same face SF .
- The point is on a difference face DF .

Similarly, for an endpoint of type A , there are two possibilities for the previous endpoint:

- The point is on an axis A .
- The point is on the same face SF (i.e., a face adjoining the axis).

Notice that for a point of type A the previous point cannot be on the face not adjoining the axis as a consequence of the Bad Faces Theorem. With this notation, we can categorize a piecewise linear path by a finite series whose elements are in the set $\{SF, DF, A, O\}$.

For a series corresponding to a finite-piece optimal path, we infer the following rules:

1. By the convexity property of optimal paths, none of the following pairs can appear in the series: (DF, DF) , (SF, SF) , (SF, A) .
2. If A appears somewhere in the series, then the end of the series cannot be (A, O) , due to the scaling and symmetry properties of optimal paths. The only exception is, of course a series which is simply (A, O) .
3. The series cannot end with (SF, O) by convexity.
4. The series cannot end with (DF, O) due to Lemma 18.

Note that rules 3 and 4 imply that the series must end with (A, O) .

We now establish part (i). Consider a path with the terminal point on say axis $F_{1,2}$ and the first segment of the path emanating from the origin. If this first segment traverses an axis, then by scaling and symmetry, part (i) immediately holds for any terminal point on an axis. By convexity, the first segment cannot be in the interior of the octant. So, the first segment must be embedded in a two-dimensional face. Now, the second segment cannot be embedded in this same face due to convexity. So, it must cross the interior and terminate either in a different face, or on the opposing axis. The first case is ruled out by Lemma 18. The second case is not possible by the Bad Faces theorem. Hence, the first, and only segment, must be embedded in an axis.

In consideration of Rules 1 through 4 above, to prove part (ii) we must exclude two remaining cases: (F, SDF_i, A, O) and (F, DSF_i, DF, A, O) , $i = 0, 1, 2, \dots$. Here SDF_i is a subsequence of (SF, DF) that repeats i times, and DSF_i is a subsequence

of (DF, SF) that repeats i times. Consider the case (F, DF, A, O) first. Without loss of generality let the terminal point be on face F_1 , denote it $v^1 = (0, v_2^1, v_3^1)$, and assume that $0 < v_2^1 \leq v_3^1$. The endpoint before v^1 has to be a point v^2 on F_2 . So $v^2 = (v_1^2, 0, v_3^2)$ which is the DF in the series. We must have $v_1^2 \leq v_3^2$ for the path to be optimal, by the assumed type of path and the Bad Faces Theorem. The next endpoint v^3 cannot be on axis $F_{1,3}$ again by the Bad Faces Theorem. Furthermore, it cannot be on axis $F_{1,2}$ due to the arguments in the proof of Lemma 18. Hence, v^3 must be in $F_{2,3}$.

Now, if the path just described is optimal, this implies that the optimal path to v^2 is from the origin to v^3 then to v^2 . Then by the scaling property, the optimal path to an arbitrary point $(u_1, 0, u_3)$ on face F_2 is of the form (F, A, O) . By symmetry, the optimal path to an arbitrary point $(0, u_2, u_3)$ on F_1 is also of the form (F, A, O) . However, v^1 is indeed of this form, which means we can replace the proposed optimal path of the form (F, DF, A, O) by a gradual path of the form (F, A, O) .

Next consider the case (F, SF, DF, A, O) . If the terminal point v is in say F_1 then so is the endpoint v^1 immediately preceding this point. This implies that the optimal path to v^1 is of the form (F, DF, A, O) . As argued above, we can eliminate this form. All the remaining cases can be eliminated by analogous arguments that reduce the end of the series to the (F, DF, A, O) case. We conclude that any optimal path to a point on the interior of a two-dimensional face can be reduced to the gradual path forms (F, A, O) or (F, O) . This establishes part (ii). \square

Finally, we present the main result for optimal paths with a finite number of

segments.

Theorem 20. *Suppose the conditions in Theorem 19 hold for an RSVP. For any point in \mathbb{R}_+^3 , if there exists an optimal path with a finite number of pieces then there exists a gradual optimal path.*

Proof. Theorem 19 establishes the result for points on the boundary of the octant. By convexity, the last segment of an optimal path to an interior point must have an endpoint on the boundary. The result then follows directly from Theorem 19. \square

4.4 Results for Exotic Paths

This entire section is devoted to arguing that certain “exotic spirals” cannot be optimal. Depicted in the left-hand side of Figure 4.2 is what we call a classic spiral, a path type which has appeared in other contexts in the literature on fluid models. In this section we show that such a path can indeed be the optimal solution to the variational problem we consider in the dissertation. For now, however, we wish to show that other types of paths, exotic spirals, cannot be better than a classic spiral. One important type of exotic spiral appears in the right-hand side of Figure 4.2. Eliminating this type of path from consideration is the focus of much of the next two results.

Lemma 21. *For any two-dimensional face, define the bisecting ray to be the ray which forms an angle of $\pi/4$ radians with the adjacent axes and whose endpoint is the origin. Consider an optimal path which the following characteristics: it contains*

Figure 4.2: Spiral paths

a line segment that intersects the bisecting ray in F_1 and it contains another line segment that intersects the bisecting ray in F_2 . Then there exists an optimal path with the following characteristics:

- (a) The path has two segments (as defined above) which form the same angle with the bisecting rays (i.e., if the segments are rotated to lie in the same face, then they must be parallel).
- (b) The path contains another segment in F_3 which intersects the bisecting ray at the same angle.
- (c) The path contains an infinite number of segments.

Proof. Let $\overline{v^0v^1} \in F_1$ and $\overline{v^2v^3} \in F_2$ be the segments which intersect the respective bisecting rays and suppose the points are traversed by the optimal path in the order v^0, v^1, v^2 , and v^3 .

We prove part (a) by contradiction, assuming the segments do not form the same angles with the bisecting rays. Consider then the portion of the path from the origin to v^1 . This portion can be rotated and scaled to create an optimal path which passes through the point, call it w , where $\overline{v^2v^3}$ intersects the bisecting ray in F_2 . Thus, we can create a path from the origin through w to v_3 which is optimal yet has a “kink” at w . However, this path cannot be optimal due to reflected convexity (Lemma 11). This establishes (a).

It is clear by rotation, scaling, and merging that one can form an optimal path to v_3 which intersects the bisecting ray in F_3 . Repeating the process results in the formation of an optimal path with an infinite number of such segments. This establishes (b) and (c). \square

Theorem 22 (Elimination of Exotic Spirals). *Consider an RSVP with $\Gamma = I$, $\theta_0 < 0$, $r_1, r_2 \geq 0$. For any optimal path to a point on the axis with a countably infinite number of segments, there exists another path, with lower or equal cost, which is of the form of the classic spiral (i.e., of the form (A, A, A, \dots, O)).*

Proof. We begin with a general principle that holds for paths with an infinite number of segments. Consider an optimal path characterization which begins with an A and contains another A at position n , elsewhere in the sequence. Then there exists an optimal path whose entire characterization must be identical to the (original) characterization starting at position n . This principle follows directly by scaling, rotation, and merging and it can be thought of as enforcing a “self-similarity” property of optimal paths. As an example, consider an optimal path of the form $(A, AS, A, A, A, A, \dots, O)$

where AS is an arbitrary subsequence. The principle implies that such a path can be replaced by a classic spiral of the form (A, A, A, \dots, O) .

Now, consider the terminal point of an optimal path, which by assumption lies on an axis and which by our convention is represented by the first A in the sequence characterizing this path. If the next endpoint lies on an axis, then the path is a classic spiral (or can be replaced by one), based on the principle above. So suppose this is not the case. The second endpoint cannot be on a different face (DF) by the Bad Faces Theorem (Theorem 13). Thus the only remaining possibility is that the second endpoint is characterized as SF , that is, it lies on the interior of one of the two adjoining faces.

Next, in any place in the sequence only a DF can follow SF by convexity and the Bad Faces Theorem. After a DF , either an SF or an A may follow (DF cannot follow, again by convexity). Finally, between any two appearances of an A in the sequence, the SF and DF sequences can be assumed to be the same, again invoking the self-similarity principle above. Putting all of these observations together, we conclude that apart from the classic spiral case, there are only two other general categories of paths with an infinite number of segments:

- (i) (A, SDF, O) , where (SDF) is an infinite subsequence of (SF, DF) .
- (ii) $(A, SDF_i, A, SDF_i, A, SDF_i, \dots, O)$, $i = 1, 2, 3, \dots$.

We now proceed to eliminate these two types of paths.

Part (i). We consider first a path of type (A, SDF, O) . Without loss of generality, assume that the terminal point (the first A in the sequence) is e_3 and the

next pivot point is $v^1 \in \text{int}(F_2)$. Now the farthest face from v^1 can be either F_1 or F_3 (since the point is on F_2 , this cannot be the farthest face). Suppose v^1 is strictly closer to F_1 . Then by the Bad Faces Theorem, the next endpoint must be in F_1 . However, such a path can be eliminated from consideration by Lemma 15. Therefore we assume that v^1 is closer to F_3 than F_1 and the next endpoint in the path is in F_3 again by the Bad Faces Theorem. (If v^1 is equidistant to F_1 and F_3 , then the segments to F_1 and F_3 have the same costs and we choose the segment going to F_3). The next point, v^3 is also in the interior of F_3 due to our assumption on the path type. Using arguments from the proof of the Bad Faces Theorem, it can be shown that v^2 must be closer to F_2 than F_1 . Next, if v^3 is closer to F_2 than F_1 then the resulting path is of “switchback” form. Such a path is suboptimal by Lemma 14. Thus, v^3 must be closer to F_1 than F_2 . Furthermore, by Lemma 21, $\overline{e_3 v^1}$ is rotationally parallel to $\overline{v^2 v^3}$. Hence, after e_3 the faces containing the endpoints are in this order: $F_2, F_3, F_3, F_1, F_1, F_2, F_2, \dots$. By the usual arguments using rotation and scaling, all the DF segments are rotationally parallel. So, for this path type, the path is an “exotic spiral” as depicted in the right half of Figure 4.2.

In the remainder of the proof, we argue that such exotic spirals cannot be optimal. Assume that $v^1 = (v_1^1, 0, v_3^1)$ and $v^2 = (v_1^2, v_2^2, 0)$. Based on rotational symmetry and scaling, there exists a k , $0 < k < 1$, such that $v^3 = (kv_3^1, kv_1^1, 0)$ and $v^4 = (0, kv_1^2, kv_2^2)$ for this assumed optimal path. This path travels from v^4 to v^1 with a cost $\tilde{J}_0(v^1 - v^2) + \tilde{J}_3(v^2 - v^3) + \tilde{J}_0(v^3 - v^4)$. We would like to construct another path from v^4 to v^1 that has a lower cost. Here we have all $v_1^1, v_3^1, v_1^2, v_2^2 > 0$ so none of the four points lie on an axis. Construct $\bar{v}^2 = (v_1^2 - x, v_2^2 - x, 0)$ and

$\bar{v}^3 = (kv_3^1 - x, kv_1^1 - x, 0)$. As $v^2, v^3 \in \text{int}(F_3)$, there always exists $x > 0$ to guarantee that $\bar{v}^2, \bar{v}^3 \in F_3$. It is clear that $\tilde{J}_3(v^2 - v^3) = \tilde{J}_3(\bar{v}^2 - \bar{v}^3)$ so it is sufficient to compare $\tilde{J}_0(v^1 - v^2) + \tilde{J}_0(v^3 - v^4)$ with $\tilde{J}_0(v^1 - \bar{v}^2) + \tilde{J}_0(\bar{v}^3 - v^4)$. Let $f(x) = \tilde{J}_0(v^1 - \bar{v}^2) + \tilde{J}_0(\bar{v}^3 - v^4)$. It is clear that $f(0) = \tilde{J}_0(v^1 - v^2) + \tilde{J}_0(v^3 - v^4)$ so it is sufficient to show that $f'(0) < 0$. It can be shown that

$$f'(x) = \|\theta\| \left(\frac{(v_1^1 - v_1^2 - v_2^2 + 2x)}{\|v^1 - \bar{v}^2\|} + \frac{(kv_1^2 - kv_1^1 - kv_3^1 + 2x)}{k\|v^1 - \bar{v}^2\|} \right).$$

So

$$f'(0) = -\frac{\|\theta\|}{\|v^1 - \bar{v}^2\|} (v_3^1 + v_2^2) < 0.$$

This means that the exotic spiral path that we assumed to be optimal in this part is never optimal as it can always be replaced by a better path.

Part (ii). We now turn our attention to the other general type of exotic spiral, one with the characterization $(A, SDF_i, A, SDF_i, A, SDF_i, \dots, O)$, $i \in \{1, 2, 3, \dots\}$ where each SDF_i is a sequence with SF/DF segments repeated i times. By symmetry and scaling arguments, we can assume that each of these sequences is identical. Suppose that the end point v^0 is on axis $F_{1,2}$ and the SF is from v^1 on F_1 . By Lemma 15, since v^2 is on a different face than v^1 , v^1 must be closer to $F_{1,3}$ than to $F_{1,2}$ and v^2 must be in F_3 . The next point, v^3 , is either on axis $F_{2,3}$ or in F_3 . However, it must be closer to $F_{2,3}$ than to $F_{1,3}$. Then based on Lemma 21, there exists point u on axis $F_{1,3}$ for which an optimal path to u contains $\overline{v^3 v^2}$. By scaling and symmetry, this path can be assumed to be of the $(A, SDF_i, A, SDF_i, A, SDF_i, \dots, O)$ form posited for the path to v_0 . Now, by assumption, there are i SF/DF segments between v^0 and the next point on the axis and of course this path passes through v_2 . Considering the

optimal path to u , since it also passes through v_2 en route to u , the portion of the this path to v_2 can be replaced by the optimal path to v_0 , up to v_2 . This patching process forms another optimal path to u . Since there are i SF/DF segments between v^0 and the next axis point, there are then $i - 1$ SF/DF segments between u and this same point. Therefore we have constructed an optimal path to a point on the axis (u) which is of the form $(A, SDF_{i-1}, A, SDF_{i-1}, A, SDF_{i-1}, \dots, O)$. Hence, there must exist an optimal path of the same form to v_0 . Repeating this patching process results in the construction of an optimal path to v_0 (and thus any point on any axis) of the form $(A, A, A, \dots, 0)$.

It remains to be argued that there must be a finite number of segments between in an optimal path between any two axis points. We only give an outline here. Consider a path with an infinite number of segments which converge to a point v_0 on $F_{1,2}$. There must be an infinite number endpoints of such segments in an ϵ -ball around v_0 . Furthermore, by Lemma 14 there must exist an infinite subsequence of endpoints for which the other terminal point of the segment is in F_3 . The cost of all such segments can be uniformly bounded away from zero (using the infimum of the cost from the ϵ -ball to F_3 , which is strictly positive). This implies however, that the total cost of any such path is infinite. Hence, the path cannot be optimal. \square

Chapter 5

Computational Method and an Example

We provide the numerical consideration for the RSVP in the first section. We outline the method to determine the optimal path and the computational method to realize that. In the second section we include an example, analytically prove that the spiral path is optimal for that example and calculate the corresponding cost.

5.1 Computational Methods

In numerical computation, there is a very important assumption that we only consider gradual paths and spiral paths. El Kharroubi et al. in [16] also compare these two types of paths and derive the analytical formulas for calculating path costs. Since we only consider the RSVP, the problem is more straight forward. The following is the scheme for the computational method. To determine the optimality between gradual path and spiral path, we need the following theorem. In the theorem, we define a spiral path to a point in the interior of the space is defined as a spiral path to some point on the face plus one direct path from that point to the interior.

Theorem 23. *For an RSVP in three dimensions, suppose that the optimal path is either the gradual path or the classic spiral path. The sufficient and necessary*

condition for a classic spiral path to be optimal is that there exists a $k > 0$ such that

$$\tilde{J}_{2,3}(ke_1) + \tilde{J}_2(e_3 - ke_1) < \tilde{J}_{1,2}(e_3),$$

or

$$\tilde{J}_{1,3}(ke_2) + \tilde{J}_1(e_3 - ke_2) < \tilde{J}_{1,2}(e_3).$$

Proof. If $\tilde{J}_{2,3}(ke_1) + \tilde{J}_2(e_3 - ke_1) < \tilde{J}_{1,2}(e_3)$ for some k then it is clear that $k < 1$ otherwise $\tilde{J}_{2,3}(ke_1) \geq \tilde{J}_{1,2}(e_3)$ by scaling and rotational symmetry. Consider the first part of LHS. By scaling and rotational symmetry $\tilde{J}_{2,3}(ke_1) > \tilde{J}_{3,1}(k^2e_2) + \tilde{J}_3(ke_1 - k^2e_2)$. So we have

$$\tilde{J}_{3,1}(k^2e_2) + \tilde{J}_3(ke_1 - k^2e_2) + \tilde{J}_2(e_3 - ke_1) < \tilde{J}_{1,2}(e_3).$$

By iterating this procedure as $k < 1$ one can easily generate a spiral path whose cost is smaller than $\tilde{J}_{1,2}(e_3)$. Thus spiral path to e_3 is optimal. As the spiral path actually can be scaled to cover all boundary points, the spiral path is optimal to all points on the faces and hence to all the points in the interior. On the other hand, assume that there exists a spiral path which is optimal to e_3 and that path goes through $ke_1, k^2e_2, k^3e_3, \dots$. If $\tilde{J}_{2,3}(ke_1) + \tilde{J}_2(e_3 - ke_1) \geq \tilde{J}_{1,2}(e_3)$, then similarly, $\tilde{J}_{2,3}(ke_1) \leq \tilde{J}_{3,1}(k^2e_2) + \tilde{J}_3(ke_1 - k^2e_2)$. This way we can construct the spiral path, which we claim is optimal. However, it does not have a lower cost than $\tilde{J}_{1,2}(e_3)$ based on the computation above, which is a contradiction. Thus the necessity of the condition is also established. \square

A spiral optimal path can be of two types: clockwise or counter-clockwise. To determine which one is better there is a very simple rule.

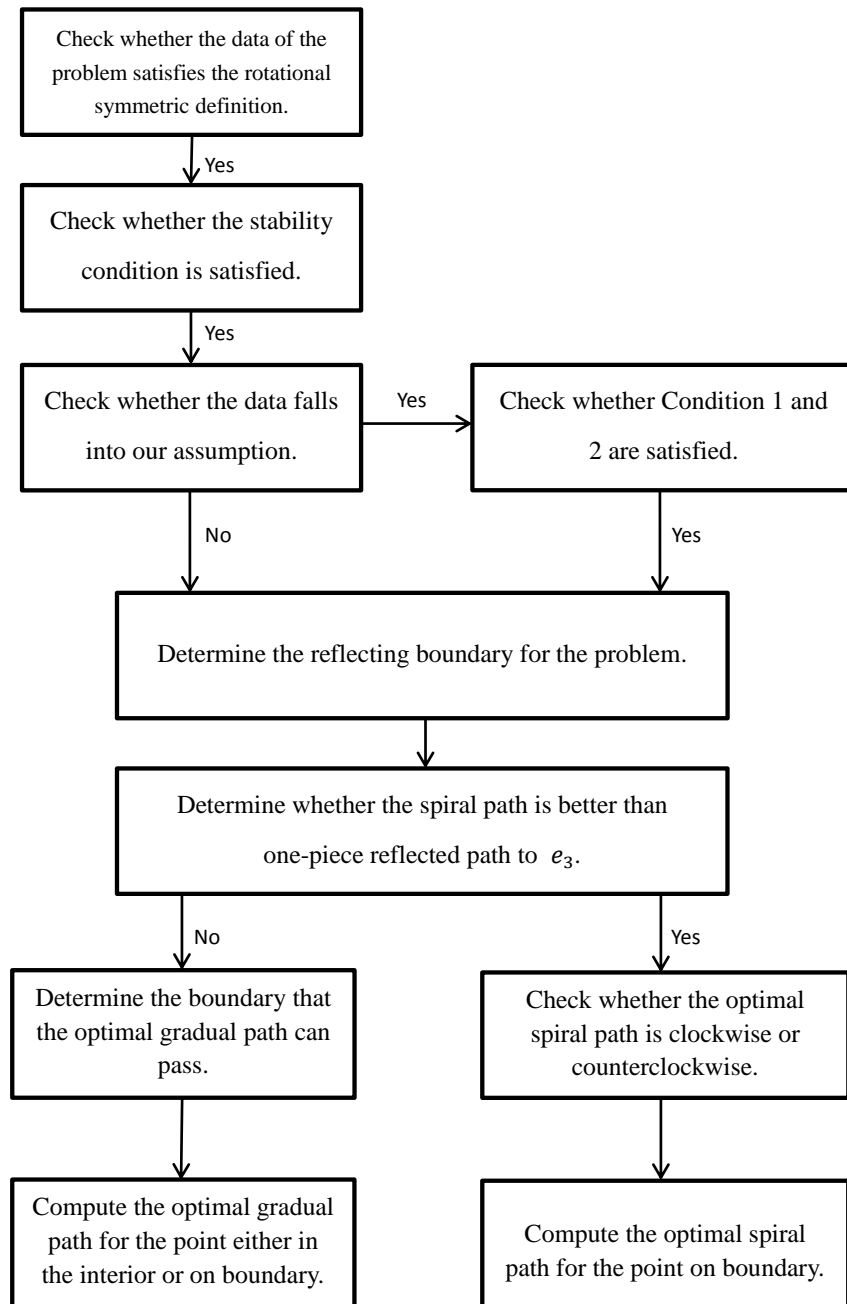

Figure 5.1: A simple computational method

Corollary 24. *In an RSVP, when $r_1 > r_2$ and $0 < k < 1$, then the spiral path that contains $(e_3, ke_1, k^2e_2, k^3e_3, \dots)$ is better than the spiral path that contains $(e_3, ke_2, k^2e_1, k^3e_3, \dots)$.*

Proof. Using the method in Lemma 16, it is clear that $\tilde{J}_2(e_3 - ke_1) < \tilde{J}_1(e_3 - ke_2)$.

Applying this to all the pieces in the spiral path we establish the result. \square

It is worthwhile to mention here that if we find $\tilde{J}_{2,3}(ke_1) + \tilde{J}_2(e_3 - ke_1) < \tilde{J}_{1,2}(e_3)$ there is no guarantee that the optimal spiral path is generated by the k that makes $\tilde{J}_{2,3}(ke_1) + \tilde{J}_2(e_3 - ke_1)$ have lowest cost. Assuming $r_1 > r_2$, the cost of the optimal spiral path to e_3 has the form

$$I_{sp}(e_3) = \frac{\tilde{J}_2(e_3 - ke_1)}{1 - k}.$$

This formula is complicated at a glance. However, when the data is given, it is no more than a quadratic function of k and it is easy to obtain the optimal k analytically. Actually in the numerical computation, we do not need to use this formula. We can easily use a grid method to divide the interval $[0, 1]$ into many pieces and calculate the corresponding cost for a spiral path based on different k values in this interval. For a gradual path, El Kharroubi et al. [16] provide the method to calculate the path cost and that can be applied here. Also in practice, we can use a grid method to get the corresponding cost.

Finally, it needs to mention that we do not calculate the cost of spiral path to the point in the interior since it still remains an open question to determine the place for the optimal path to finally leave boundary.

5.2 An optimal spiral path example

In Example 2 of Section 6 of El Kharroubi et al. [16], it is shown that a spiral path has a lower cost than a two-piece gradual path, for the corresponding RSVP. Here we give a related example, and using the results of previous sections, show that a spiral path is indeed optimal.

Let $\theta = (-1, -1, -1)'$, $\Gamma = I$ and

$$R = \begin{pmatrix} 1 & 0 & \frac{3}{2} \\ \frac{3}{2} & 1 & 0 \\ 0 & \frac{3}{2} & 1 \end{pmatrix}.$$

To establish that a spiral path is optimal, we need to undertake three steps. First, we check that Conditions 1 and 2 of Chapter 4 hold. If so, then we know that only gradual paths or spiral paths are optimal. Second, using results from [16] we check the reflectivity characteristics of optimal paths traversing an axis. Third, to travel to a point, say e_3 , on an axis, we verify that it is less costly to traverse one of the other axes and then cross a two-dimensional face. If this is the case, then one can construct a spiral path to e_3 that is cheaper than the gradual path to e_3 (which simply travels along the axis).

The next proposition simplifies the process of checking Conditions 1 and 2 and may be useful in producing other examples.

Proposition 25. *For a RSVP with $r_2 = 0$ and $0 < r_1 < 2$ Conditions 1 and 2 hold.*

Proof. Clearly $(r_1, r_2) \in R_f$ under the assumptions given. Recall that Condition 1 is

given by

$$(1 + r_2^2)(1 + r_1^2 - r_2 - r_1 r_2)^2 \geq 2(r_1 r_2)^2(1 + r_1^2 + r_2^2 - r_1 - r_2 - r_1 r_2). \quad (5.1)$$

For $r_2 = 0$ the condition reduces to $(1 + r_1^2)^2 > 0$ which clearly holds for all real r_1 .

Next, to check Condition 2, it is sufficient to establish that for all $v = (v_1, 0, 1) \in F_2$ and $v' = (0, v_2, v_3) \in F_1$ the following expression is non-negative:

$$[(1 + r_1 + r_2)T^* + r_1 v_2 + r_2(v_3 - 1)]^2 - (1 + r_1^2 + r_2^2)(2T^* v_1 - v_1^2). \quad (5.2)$$

By basic algebra, for any real T^* and v_1 we have $2T^* v_1 - v_1^2 \leq (T^*)^2$. Using this, plus $r_1 > 0$ and $r_2 = 0$ yields the following (non-strict) lower bound on (5.2):

$$[(1 + r_1)T^*]^2 - (1 + r_1^2)(T^*)^2 = (T^*)^2[(1 + r_1)^2 - (1 + r_1^2)] \geq 0.$$

Therefore, Condition 2 also holds. □

So, the proposition provides verification of Conditions 1 and 2 for the example in this section. Next, we use results from [16] to check reflectivity of the axes. In particular we use equations (24) and (25), Remark 2, and Proposition 1 from that paper. Let $R_1 = (1, 3/2, 0)'$, $R_2 = (0, 1, 3/2)'$, and $R_{1,2} = (R_1, R_2)$. Define $A_{1,2} = I - R_{1,2}B_{1,2}$ and $B_{1,2} = (R'_{1,2}R_{1,2})^{-1}R'_{1,2}$. Some algebra shows that

$$\frac{\|A_{1,2}\theta\|}{\|A_{1,2}e_3\|}B_{1,2}e_3 - B_{1,2}\theta \approx (0.0526, 1.5526) > 0.$$

So optimal one-piece reflected paths confined to an axis use both corresponding reflection vectors.

Finally, we check the spiral condition for the point e_3 . In particular either

$$\tilde{J}_{1,2}(e_3) \geq \tilde{J}_{\{2,3\},2}^2(e_3) \quad \text{or} \quad \tilde{J}_{1,2}(e_3) \geq \tilde{J}_{\{1,3\},1}^2(e_3)$$

must hold. We verify the first inequality. For the parameters of our example we have

$$\tilde{J}_{1,2}(e_3) = \|A_{1,2}\theta\| \|A_{1,2}e_3\| - \langle A_{1,2}\theta, A_{1,2}e_3 \rangle \approx 0.4211.$$

Next, let $u = (0.5, 0, 0)$. Then

$$\tilde{J}_{\{2,3\},2}^2(e_3) \leq \tilde{J}_{2,3}(u) + \tilde{J}_2(e_3 - u) \approx 0.3317 < \tilde{J}_{1,2}(e_3).$$

Therefore, for the given RSVP, the optimal path to any point on the boundary of the octant is a classic spiral optimal path.

We then more precisely characterize this optimal spiral path. In particular, the last piece connects the points ke_1 and e_3 , where k , $0 < k < 1$. The optimal value of k can be calculated by the corresponding spiral cost as a function of k :

$$f(k) = I_{sp}(e_3) = \frac{\tilde{J}_2(e_3 - ke_1)}{1 - k}.$$

Applying the data for this problem and setting $f'(k) = 0$ results in the quadratic root-finding problem $1228123k^2 - 3690960k + 1626300 = 0$. The appropriate root is $k^* \approx 0.5363$. From this we can calculate the cost of the optimal spiral as

$$\frac{\tilde{J}_2(e_3 - k^*e_1)}{1 - k^*} \approx 0.2384.$$

Chapter 6

Conclusions and Future Work

In this dissertation, we have shown the optimal paths for RSVP's in 3-D can be restricted to two types: gradual and spiral. We expect this result holds for all RSVP's in 3-D, but our current results rely crucially on two numerical conditions and only hold when r_1 and r_2 are non-negative and the covariance matrix is the identity. In Chapter 3 we provide the stability conditions for the RS-SRBM. We simplify the conditions to an inequality based on Bramson et al. [5]. All our further results are under the stability conditions. Chapter 4 contains a variety of results that contribute to the main result that only two possible path types can be optimal. It needs to be noted that not all those theorems require non-negative r_1 and r_2 and an identity covariance matrix. Nonetheless, at this point the main result clearly requires the most restrictive of the conditions in the supporting results. In chapter 5, we provide the computational method to calculate the cost for RSVP in 3-D. Naturally, the computational method can be applied even in cases for which the main result has not been established. Further, we provide an example in which the spiral case is optimal. For this example, the two conditions are completely verified so that this optimality does not require any further assumptions. The following list summarize work in progress and potential future work:

1. Relax the parameter restrictions and remove the conditions.

Currently our result relies on the fact that r_1 and r_2 are non-negative and the covariance matrix is identity. The big disadvantage of positive r_1 and r_2 is that such parameters may not correspond to "standard" queueing networks. Since actually only a few theorems we currently use require non-negative r_1 and r_2 it is possible that we can relax these assumptions. At the same time, if we could remove at least Condition 2, optimal path verification would be more analytically rigorous. To relax the covariance matrix is more complicated since some of the important results such as Lemma 14 are no longer true. So, relaxing this condition will likely require more mathematical innovation.

2. Beyond the Symmetric Case.

Our hope is that the path properties we establish can be extended beyond the symmetry cases. However, it should be noted that the general case in three dimensions is already known to be fairly complex and in fact our main results do not hold for all parameter cases in three dimensions. In [15], the authors show that an optimal path to a point in the interior of the octant may have up to five linear pieces, implying that a simple characterization of paths in the general $d = 3$ case is non-trivial. In that example

$$R = \begin{pmatrix} 1 & -\frac{1}{3} & -\frac{1}{3} \\ \frac{1}{10} & 1 & -\frac{1}{3} \\ -\frac{1}{3} & \frac{1}{10} & 1 \end{pmatrix},$$

$\theta = (-1, -11, -111)'$ and $v = (1, 21, 211)$. This five-piece path is depicted in

Figure 6.1: An Optimal Path with Five Pieces

Figure 6.1. Nonetheless, we believe that deriving new properties of optimal paths for special cases is a necessary building block for solving other variational problems, and provides for a better understanding of the tail asymptotics for SRBM.

3. Extension of the RSVP into Higher Dimensions.

Another more advanced topic is to extend the RSVP into higher dimensions. One major problem in high dimensions is the possible existence of “super-spirals.” This is a path that is spiral in general and the portions on different faces are also spirals themselves. (Faces are at least 3-D here.) This seems to lead to an intractable farrago of cases. Another problem with higher dimensional problems is the LDP and stability conditions. The LDP has been proven

for many cases in three dimensions. However, the LDP theory is unresolved in most higher dimensional cases. The stability conditions for SRBM in higher dimensions have not yet been established. Nonetheless, it is still valuable to investigate the MS-SRBM problem in higher dimensions to gain insight into optimal path behavior.
